7.1 Unit Testing 78
7.2 Integration Testing 79
7.3 Stress Testing 80
7.4 Edge Case Analysis 81

CHAPTER 1 Introduction & Objectives

In the modern computing landscape, network connectivity is ubiquitous and indispensable. Every process on a Linux system — whether a user application, a system daemon, or a background service — routinely establishes network connections to communicate with remote hosts. While this connectivity enables powerful functionality, it also creates significant challenges for system administrators, security analysts, and developers who need to understand precisely what is happening on their machines at the network level. The sheer volume of concurrent connections observed on a modern workstation — hundreds of simultaneous TCP sessions across dozens of processes — makes manual inspection infeasible.

The Linux networking stack has evolved considerably since the original socket API was introduced. Modern kernels implement a fully asynchronous, multi-queue networking subsystem that processes packets at line rate using NAPI (New API) polling, hardware offload features such as TSO/GSO/GRO, and receive-side scaling (RSS) across CPU cores. Netfilter, introduced by Rusty Russell in 1998 and shipped as part of the mainline kernel since 2.4, provides five hook points in the IPv4 and IPv6 packet processing paths that allow kernel modules to inspect and modify every packet. These hooks form the foundation of iptables, nftables, and — crucially — KTA.

The case for operating at the kernel level rather than in userspace is compelling from both a completeness and a performance perspective. Userspace tools that read /proc/net/tcp operate on a snapshot that is already stale by the time the read completes; connections that open and close within a single polling interval are permanently lost. In contrast, a netfilter hook sees every packet before any userspace process has a chance to read a socket, providing true completeness. Furthermore, the kernel can aggregate statistics across hundreds of connections with microsecond latency that no userspace polling mechanism can match.

The evolution from BPF (Berkeley Packet Filter, 1993) to eBPF (extended BPF, introduced in kernel 3.18 in 2014) represents the state of the art in kernel-level observability. eBPF allows verified bytecode programs to be injected into the kernel at runtime, attaching to tracepoints, kprobes, and network events without requiring a kernel module. Tools such as Cilium, Falco, and bpftrace are built on eBPF. However, eBPF programs face strict limits: the verifier rejects programs with more than one million instructions (pre-kernel 5.1), loops are constrained, and state must be managed through kernel-side maps. For a complex monitoring suite that maintains connection tables, DNS caches, anomaly detectors, and route stores, a kernel module written in C offers cleaner state management, unrestricted loop constructs, and direct access to all kernel data structures — at the cost of requiring more rigorous development discipline.

The Kernel Traffic Analyzer (KTA) was conceived and implemented during the final year of a B.Tech Computer Science & Engineering programme at a time when the author was working through a 4G mobile hotspot in Bhopal, Madhya Pradesh, India. The experience of being unable to determine which applications were consuming the limited mobile data allocation, which countries the data was transiting, and whether any anomalous activity was occurring in the background provided the immediate motivation for the project. KTA v7.0 represents

approximately twelve thousand lines of code across C, C++, and Python — the culmination of seven major development iterations — and addresses all five research gaps identified in the literature.

Despite the maturity of the Linux networking ecosystem, no single open-source tool available as of 2024 simultaneously provides kernel-level connection tracking, per-process attribution, real-time DNS correlation, geographic route visualisation, anomaly detection, and integrated remediation. This gap is not merely inconvenient — it has real security consequences. Industry reports from Verizon (DBIR 2023) indicate that 74% of breaches involved the human element, but a significant fraction of the remainder involved malware or compromised software that exfiltrated data silently over months. In such scenarios, the ability to immediately attribute every outbound byte to a specific process and destination country could dramatically reduce dwell time — the median time between breach and detection, which the 2023 IBM Cost of a Data Breach Report places at 204 days.

Consider a concrete scenario: a developer installs an npm package that includes a supply-chain attack payload. The payload opens a reverse shell to a C2 server in a foreign country. With existing tools, the developer would need to cross-reference netstat output (showing an open TCP connection), DNS resolver logs (showing a suspicious domain resolution), and router logs (showing outbound traffic) to detect the activity. KTA surfaces this in a single screen: the Connections tab shows the node process with ESTABLISHED state, the DNS Map tab shows the domain resolved seconds before the connection, the Route Map animates the hop path through foreign ASNs, and the Anomalies tab may flag HIGH_BW if data is being exfiltrated at speed.

The following six critical deficiencies in existing tools are addressed by KTA:

- **No kernel-level visibility:** Userspace tools like ss and netstat only read /proc/net/tcp and miss packets that bypass the socket layer or belong to short-lived connections. High-frequency connections that open and close within one polling cycle are silently dropped from the monitoring record entirely.
- **Lack of per-process attribution:** Raw packet capture tools such as tcpdump operate at the interface level and do not attribute traffic to specific OS processes or executable paths. An analyst cannot determine whether a connection originated from Firefox, a malicious background daemon, or a compromised library.
- **No real-time DNS correlation:** Knowing that a connection goes to 142.250.77.46 is far less meaningful than knowing it goes to google.com. DNS correlation must happen at packet interception time to be useful; post-hoc DNS resolution is unreliable because the DNS record may have been updated or the TTL may have expired before the correlation is attempted.
- **No geographic routing awareness:** Administrators cannot easily determine which countries their data transits through, nor detect unexpected routing changes that could indicate BGP hijacking or route leaks. Mobile hotspot users behind carrier-grade NAT face additional challenges because ICMP traceroute is typically blocked.
- **Fragmented anomaly detection:** Security teams rely on separate SIEM tools for anomaly detection, creating latency between an event and its detection. Kernel-level detection with

sub-second latency is achievable and eliminates the need for external tooling for common anomaly types.

- **No integrated firewall control:** Blocking a suspicious connection typically requires switching to a terminal and writing iptables rules manually, interrupting the monitoring workflow and delaying response by tens of seconds.

Seven primary objectives were defined at the outset of the project. Each objective corresponds to a specific technical gap identified in Section 1.2 and is directly traceable to an implemented subsystem in KTA.

Objective 1 — Kernel-level packet interception: Design and implement a Linux kernel module that intercepts all TCP and UDP traffic at the NF_INET_LOCAL_IN and NF_INET_LOCAL_OUT netfilter hooks without dropping any packets. The hooks must operate at NF_IP_PRI_FIRST priority to ensure they run before connection tracking, and must return NF_ACCEPT unconditionally so that network functionality is not impaired. This objective establishes the foundation upon which all other features are built.

Objective 2 — Per-process attribution: Implement per-process attribution by correlating kernel sockets to PIDs using a multi-level cache hierarchy (sock_cache, inode_cache, flow_cache, full resolver). The design rationale for the four-level hierarchy is to minimise the frequency of expensive for_each_process() scans: sock_cache hits take O(1) time, inode and flow cache hits take O(log n), and only the full resolver requires walking the process list. The target attribution accuracy is above 95% for TCP connections with duration exceeding 500 ms.

Objective 3 — In-kernel DNS parsing: Parse DNS responses in RFC 1035 wire format within the netfilter hook to build a real-time IP→domain mapping cache available at connection creation time. The design rationale is that DNS responses always precede the TCP SYN that opens the connection; by parsing the DNS response in the incoming hook (NF_INET_LOCAL_IN) before parse_packet() runs, the domain name is inserted into dns_map before the connection entry is created.

Objective 4 — Route daemon with geo-enrichment: Integrate a Python-based route daemon that performs TCP traceroute on port 443 and enriches each hop with MaxMind GeoLite2 city, country, latitude/longitude, ASN, and organisation data. The use of TCP mode (traceroute -T) rather than ICMP is motivated by the deployment environment: 4G NAT typically blocks ICMP but passes TCP SYN packets on port 443 to enable legitimate HTTPS traffic.

Objective 5 — Anomaly detection: Implement five lightweight anomaly detection algorithms (port scan, SYN flood, connection burst, high connection count, high bandwidth) operating entirely within the kernel using per-process velocity trackers. The kernel-only design ensures detection latency is bounded by the 1-second rate window rather than by any IPC or polling round-trip.

Objective 6 — Proc interface and Qt6 GUI: Expose all collected data through seven /proc file interfaces consumed by a Qt6 GUI refreshing every second across 15 specialised monitoring tabs. The proc-file contract decouples the kernel module from the GUI, allowing the GUI to be updated or replaced without modifying kernel code.

Objective 7 — Integrated remediation: Provide one-click firewall control (iptables), bandwidth throttling (tc-netem), data export to JSON/CSV/PDF, and a system tray with anomaly badge

notifications. The design rationale is that monitoring without the ability to act is incomplete; a network analyst should be able to respond to a detected threat within seconds without leaving the KTA interface.

The scope of this project covers IPv4 and partial IPv6 (last 32 bits stored) TCP and UDP traffic on Ubuntu 22.04 LTS with Linux kernel 6.8.0. The system monitors the local machine only and does not perform deep packet inspection beyond DNS response parsing. The firewall and throttling features apply to OUTPUT traffic via iptables and tc-netem respectively.

The following limitations were accepted as part of the project scope:

- Full IPv6 128-bit address tracking is not implemented. The flow_key struct stores only 32 bits of the IPv6 source and destination address. This is flagged as future work and does not affect IPv4 monitoring, which is the primary use case.
- Route tracing relies on traceroute which requires root privileges. On networks where even TCP SYN on port 443 is rate-limited or blocked, hop discovery may be incomplete.
- The connection table is capped at 2,048 entries. Under sustained high-traffic conditions (observed peak: 1,847 entries), older CLOSED entries are evicted to make room for new connections.
- MaxMind GeoLite2 databases require a free account registration and periodic manual updates. The accuracy of city-level geolocation varies by region; ASN-level accuracy is typically above 99%.
- The SparklineDelegate in the Qt6 GUI must not inherit QObject (no Q_OBJECT macro) due to a vtable linker conflict with QStyledItemDelegate. This is a known Qt limitation that prevents using signals/slots directly in sparkline rendering.
- The module version string in the kernel module reports 7.0 but the README in the GitHub repository still reads 6.0 due to documentation not being updated after the final version increment.

The remainder of this report is structured as follows. Chapter 2 presents a comprehensive literature survey of existing network monitoring techniques, kernel-level packet capture approaches, DNS analysis methods, geographic routing tools, and anomaly detection frameworks. Chapter 3 identifies the research gaps and presents the proposed system architecture with detailed module design. Chapter 4 presents experimental results. Chapter 5 draws conclusions and outlines future directions. Chapter 6 provides implementation details for key subsystems. Chapter 7 describes the testing and validation approach. References and appendices follow.

KTA represents a contribution to the open-source network security and observability ecosystem that is distinctive in its combination of depth and breadth. While individual capabilities such as kernel packet capture or DNS monitoring exist in separate tools, no comparable open-source project integrates all of them in a single installable kernel module with a production-quality GUI. The project demonstrates that a single developer, working within the constraints of a final-year B.Tech project timeline, can build a system of this complexity using freely available tools and

publicly documented kernel APIs.

From an educational perspective, KTA serves as a reference implementation for several advanced Linux kernel programming techniques: softirq-safe spinlock usage (spin_lock_bh), RCU read-lock protected task structure access, GFP_ATOMIC memory allocation in interrupt context, workqueue-based deferred work scheduling, and /proc filesystem virtual file implementation. These topics are typically covered only in advanced kernel development courses and are rarely demonstrated in conjunction with a complete application-level consumer (the Qt6 GUI).

From a practical security perspective, KTA addresses a real need in the Indian developer and SME community where dedicated network monitoring appliances are cost-prohibitive. A free, open-source tool that runs on commodity hardware with a 4G internet connection provides visibility that was previously available only to enterprises with dedicated SOC (Security Operations Centre) infrastructure.

The following table defines key terms and abbreviations used throughout this report.

Term / Abbreviation	Definition
ASN	Autonomous System Number — a globally unique identifier assigned to a collection of IP address ranges u
BPF / eBPF	Berkeley Packet Filter / extended BPF — a kernel virtual machine that executes sandboxed programs in ke
BGP	Border Gateway Protocol — the inter-domain routing protocol of the internet, used by ASNs to advertise IP
CLOSED	TCP connection state after both FIN/ACK exchange is complete and the connection entry is eligible for evic
DNS	Domain Name System — the hierarchical naming system that maps human-readable domain names to IP a
FIN_WAIT	TCP state after the local endpoint has sent FIN, awaiting the remote FIN+ACK.
flow_key	KTA internal struct: {src_ip, dst_ip, src_port, dst_port, proto} identifying a unique 4-tuple after make_canoni
GFP_ATOMIC	Linux kernel memory allocation flag meaning "do not sleep" — required for all allocations in softirq/interrupt
GeoLite2	MaxMind's free-tier IP geolocation database providing city, country, and ASN data.
GUI	Graphical User Interface — in KTA context, the Qt6 C++ application.
inode_cache	KTA second-level cache mapping socket inode numbers to PIDs.
iptables	Linux userspace firewall administration tool that manages netfilter rules.
KTA	Kernel Traffic Analyzer — the system described in this report.
NF_ACCEPT	Netfilter verdict meaning "continue normal packet processing" — returned by all KTA hooks.
NF_INET_LOCAL_IN	Netfilter hook point for packets destined to the local machine (post-routing).
NF_INET_LOCAL_OUT	Netfilter hook point for packets generated by local processes (pre-routing).
NF_IP_PRI_FIRST	Highest priority value (-300) for netfilter hook registration — ensures KTA runs before conntrack.
PID	Process Identifier — a kernel-assigned integer uniquely identifying a running process.
proc_fs	Linux pseudo-filesystem mounted at /proc, exposing kernel data structures as virtual files.

Term / Abbreviation	Definition
RFC 1035	IETF standard defining the DNS wire format for queries and responses.
RCU	Read-Copy-Update — a synchronisation mechanism for read-mostly data structures in the kernel.
skb	Socket buffer (struct sk_buff) — the primary kernel data structure for network packets.
sock_cache	KTA first-level cache mapping struct sock pointers directly to PIDs.
SYN_SENT	TCP state after the client has sent SYN, before receiving SYN+ACK.
tc / tc-netem	Linux Traffic Control — kernel subsystem for packet scheduling, shaping, and emulation.
TTL	Time To Live — a field in IP headers limiting hop count; also used in DNS records to specify cache lifetime.
UDP	User Datagram Protocol — connectionless transport protocol used for DNS, streaming, and other latency-s
workqueue	Linux kernel deferred work mechanism that executes functions in a kernel thread context (process context).

Table 1.1 — Definitions and Abbreviations

This chapter established the motivation for KTA by highlighting the limitations of existing network monitoring tools and the real security implications of inadequate network visibility. The problem statement was articulated as six specific deficiencies in existing tools. Seven project objectives were defined, each with a clear design rationale traceable to an implemented subsystem. The scope and limitations were defined honestly, including incomplete IPv6 support and the 2,048-connection table cap. The significance of the project for education, security, and the open-source community was discussed. Chapter 2 now surveys the existing literature to establish the academic context for these contributions.

CHAPTER 2 Literature Survey

This chapter surveys existing work in the areas of network traffic monitoring, kernel-level packet capture, DNS-based analysis, geographic routing, anomaly detection, and related GUI frameworks. The survey establishes the academic and technical context for the research gaps addressed by KTA and justifies the design decisions made in Chapter 3.

2.1.1 Traditional Userspace Tools

tcpdump, originally developed by Van Jacobson, Craig Leres, and Steven McCanne at Lawrence Berkeley National Laboratory in 1989, pioneered kernel-assisted packet capture through the Berkeley Packet Filter mechanism. BPF allows filter expressions to be compiled into a bytecode program that runs in kernel space to decide which packets to copy to userspace, dramatically reducing the overhead compared to copying all packets and filtering in userspace. tcpdump remains the de facto standard for command-line packet capture and is pre-installed on virtually every Linux distribution. However, it does not associate packets with processes and requires substantial manual effort to correlate output with application behaviour. It also writes raw PCAP files that require separate tools for analysis.

Wireshark (originally Ethereal, renamed in 2006) was created by Gerald Combs in 1998 and has since grown into the most widely used graphical packet analyser in the world. Wireshark dissects over 3,000 protocols, supports live capture via pcap and libpcap, and provides a powerful display filter language. The application is invaluable for protocol debugging and forensic analysis of PCAP recordings. However, it is not designed for continuous production monitoring: live capture at high packet rates consumes substantial CPU and memory, and the interface becomes unwieldy when thousands of connections are open simultaneously. Critically, Wireshark does not attribute packets to OS processes natively, though the recent addition of process information via extcap interfaces partially addresses this.

ss (socket statistics) and its predecessor netstat are included in every major Linux distribution. ss reads from kernel socket diag infrastructure (SOCK_DIAG, RFC 7395) which provides more detailed information than /proc/net/tcp but still operates on a point-in-time snapshot. The -p flag displays the PID and process name for each socket by cross-referencing /proc/[pid]/fd. The fundamental limitation is that ss shows only currently open connections: any connection that opened and closed between two ss invocations is invisible. Under typical workloads with HTTP/2 connection multiplexing and short-lived HTTPS connections, this means a significant fraction of network activity is unobserved.

nethogs, written by Arnout Engelen (originally Rob van Hoecke) around 2004, attempts to provide per-process bandwidth monitoring by parsing /proc/net/tcp periodically and correlating with socket inodes from /proc/[pid]/fd. It displays a live table of per-process bandwidth sorted by current usage. nethogs is lightweight and useful for quick bandwidth attribution but suffers from: (a) the same snapshot limitation as netstat; (b) inability to show connection destinations or DNS names; (c) no anomaly detection; (d) purely text-based interface with no history or export capability.

iftop (by Paul Warren, 2002) monitors traffic on a single network interface and displays bandwidth usage by host pair in a ncurses interface. It operates at the packet level using libpcap and can show DNS resolution for endpoints. However, it provides no per-process

attribution, no anomaly detection, no route tracing, and no persistent history. It is essentially a bandwidth monitor rather than a security-oriented observability tool.

2.1.2 Flow-Based and eBPF Monitoring

NetFlow, developed by Cisco in 1996, exports flow summaries from routers and switches to collection servers (NetFlow collectors). A flow is defined as a unidirectional sequence of packets sharing a 5-tuple (source/destination IP, source/destination port, protocol). NetFlow v9 and its open successor IPFIX (RFC 7011, 2013) add flexible field definitions and template support. NetFlow provides excellent scalability for network-wide visibility but operates at the network device level and is unavailable for monitoring an individual host's internal processes without router-side configuration. Furthermore, NetFlow discards payload content and does not attribute flows to OS processes.

sFlow (RFC 3176) takes a sampling approach, forwarding one in N packets to a collector. This reduces overhead at the cost of accuracy, making it unsuitable for security monitoring where every connection matters. For a local host monitor like KTA, sampling is not acceptable.

Extended Berkeley Packet Filter (eBPF), mainlined in kernel 3.18 (2014) with major enhancements in 4.4 (maps), 4.7 (tc/cls_bpf), and subsequent releases, has emerged as the dominant paradigm for kernel-level observability without writing a traditional kernel module. The eBPF verifier statically analyses bytecode for safety (no infinite loops, no invalid memory accesses, bounded stack usage) before loading it into the kernel. eBPF programs can attach to tracepoints (kprobes, uprobes, tracepoints, perf events) and network events (tc, XDP, socket filters). Tools built on eBPF include Cilium (network policy and observability for Kubernetes), Falco (security monitoring), Pixie (application performance monitoring), and bpftrace (DTrace-style tracing language).

Despite its power, eBPF has limitations relevant to KTA's design. The complexity limit (1 million instructions pre-5.1, raised to 2 million in 5.12+) constrains the amount of per-packet processing that can be performed in a single program. Maintaining a connection table of 2,048 entries with DNS caches and anomaly counters requires careful partitioning across multiple eBPF maps and programs, making the resulting system harder to reason about than a single-file C implementation. Additionally, eBPF requires BPF Type Format (BTF) metadata for CO-RE (Compile Once - Run Everywhere) portability, adding toolchain complexity. For an academic project with a fixed kernel version target (6.8.0), a kernel module offers a simpler and more direct path to the required functionality.

The Linux Netfilter framework, introduced by Rusty Russell in 1998 for the 2.4 kernel series, provides five hook points in the IPv4 packet processing path: NF_INET_PRE_ROUTING (before routing decision), NF_INET_LOCAL_IN (for locally delivered packets), NF_INET_FORWARD (for forwarded packets), NF_INET_LOCAL_OUT (for locally generated packets), and NF_INET_POST_ROUTING (after routing, before transmission). IPv6 has an identical set of hooks. KTA registers at LOCAL_IN and LOCAL_OUT to capture all traffic to and from the local machine — the correct position for a per-host monitor.

Hook registration uses nf_hook_ops structs specifying the hook number, priority, protocol family (NFPROTO_IPV4), and callback function pointer. KTA registers at NF_IP_PRI_FIRST (-300), which is lower than the connection tracking priority (NF_IP_PRI_CONNTRACK = -200)

and lower than NAT (-100). This ensures KTA sees the original pre-NAT packet, which is essential for correct IP-to-process attribution.

PID attribution from a netfilter hook presents a significant challenge: the hook runs in softirq context, where current may or may not point to the process that generated the packet. For outgoing packets (LOCAL_OUT), current is typically the process that called send() or write() on the socket, making direct current->pid attribution feasible. For incoming packets (LOCAL_IN), current is whatever happened to be scheduled when the packet arrived, making direct attribution impossible. KTA handles this asymmetry by: (a) using direct current->pid for outgoing packets when the socket is accessible; (b) relying on the cache hierarchy for all other cases, with async workqueue resolution for cases that miss all caches.

The sock_cache is a hash table mapping struct sock* pointers (obtained from the skb's sk field) to PIDs. This cache is populated by the workqueue resolver and hits on subsequent packets from the same socket. The inode_cache maps socket inode numbers (from sock->sk_socket -> file->f_inode->i_ino) to PIDs and is populated by scanning /proc/[pid]/fd entries in the workqueue. The flow_cache maps the 5-tuple flow_key to PIDs and acts as a fallback for UDP flows where the socket may be reused across connections. The full resolver is an expensive for_each_process() scan that walks every process and every file descriptor, comparing inode numbers; it is invoked only when all caches miss and runs asynchronously in the ta_resolver workqueue to avoid blocking the softirq path.

A critical implementation detail is the use of rcu_dereference(mm->exe_file) to obtain the executable file path for a process. In Linux kernel versions prior to 6.7, this was done via get_mm_exe_file(). That function was removed in kernel 6.7 (commit 47b9f88); KTA uses the RCU-protected direct access pattern, holding the RCU read lock with rcu_read_lock() around the dereference. This is the correct and forward-compatible approach.

Stack frame discipline is critical in netfilter hooks. The Linux kernel enforces an 8 KB kernel stack per task (historically 4 KB on 32-bit systems, configurable on 64-bit). KTA's packet processing functions keep all local variables in a single combined frame under 1,024 bytes, with larger structures allocated on the heap using GFP_ATOMIC kmalloc. This avoids stack overflow in deeply nested call chains (netfilter hook → packet_parser → stats_update → anomaly detection).

DNS is the foundational naming layer of the Internet and has been the subject of extensive security research. Paul Mockapetris designed DNS in RFC 882 (1983) and the final wire format specification in RFC 1035 (1987). DNS queries and responses use a compact binary encoding that allows domain names to be compressed using pointer references within the message. Understanding this format — including pointer compression, label encoding, and the structure of resource records — is essential for implementing a correct in-kernel parser.

Passive DNS collection, pioneered by Florian Weimer at the Computer Emergency Response Team (CERT/Bund) and presented at the FIRST conference in 2005, records all DNS responses observed on a network segment and builds a historical database of IP-to-domain mappings. This database is used for threat intelligence: by querying historical DNS, analysts can determine what domains a known-malicious IP served in the past, enabling retrospective investigation of incidents. Services like PassiveDNS, DNSDB (Farsight Security), and VirusTotal's passive DNS API implement this approach at internet scale. KTA's dns_map

implements a lightweight single-host version of this concept.

DNS-based exfiltration is a well-documented attack technique in which an attacker encodes data in DNS query labels (e.g., base32-encoded payload as a subdomain of an attacker-controlled domain) to bypass firewalls that allow DNS traffic but block direct TCP connections. Detection approaches include monitoring query volume per domain, label length distribution analysis, and entropy measurement of query names. While KTA's current implementation does not implement DNS exfiltration detection, the dns_map and DNS leak detection subsystems provide the foundation for adding it.

Pi-hole (Jacob Salmela, 2014) and AdGuard Home intercept DNS queries at the local resolver level, blocking known advertising and tracking domains by returning NXDOMAIN or a loopback address. These tools are widely deployed but monitor only queries, not the TCP connections that follow. They cannot determine which application made a given DNS query (the query comes from the local resolver's PID, not the originating application) and they do not correlate DNS resolutions with subsequent network flows. KTA takes a complementary approach: rather than blocking at the resolver, it intercepts responses at the packet level and uses the resolved domain to enrich the connection entry in the traffic table.

DNS leak detection — verifying that all DNS queries go through the configured resolver and not to external servers — addresses a common privacy concern for VPN users. When a VPN client fails to route DNS traffic through the VPN tunnel, DNS queries are visible to the ISP (DNS leak). KTA's DnsLeakTab identifies all DNS packets (UDP port 53 or TCP port 53) observed by the LOCAL_OUT hook and compares the destination IPs against the configured resolvers in /etc/resolv.conf. Any DNS query to an unexpected server is flagged as a potential leak.

DNSSEC (RFC 4033, 2005) provides cryptographic authentication of DNS responses, preventing cache poisoning attacks. While KTA does not implement DNSSEC validation (which would require a full DNSSEC resolver in the kernel — an unreasonable scope for this project), future versions could integrate with the systemd-resolved stub resolver to obtain DNSSEC validation status for each resolved domain.

MaxMind was founded in 2002 and has since become the dominant provider of IP geolocation data. The GeoLite2 databases (City and ASN variants) are freely available under a Creative Commons Attribution-ShareAlike 4.0 licence and are used in CDN routing, fraud detection, content licensing, and compliance monitoring by thousands of companies worldwide. The GeoLite2-City database maps IPv4 and IPv6 addresses to city, country, ISO country code, latitude, and longitude with an accuracy of approximately 55–80% at the city level depending on region (higher for North America and Western Europe, lower for developing regions). ASN accuracy is above 99% for publicly routable addresses. KTA stores latitude and longitude as integers multiplied by 10^6 (E6 format) to avoid floating-point in kernel structures.

The traceroute utility, written by Van Jacobson in 1987, discovers the hop-by-hop path between two hosts by sending a series of probes with increasing TTL values. When a router decrements the TTL to zero, it returns an ICMP Time Exceeded message, revealing its IP address and round-trip time. Traditional UDP traceroute uses unprivileged UDP probes on ports above 33434; ICMP traceroute (Paris-traceroute) sends ICMP Echo probes. Both modes are frequently blocked by firewalls and NAT devices. TCP traceroute (traceroute -T) sends TCP SYN packets on a specified port and relies on the same TTL mechanism. Port 443 (HTTPS) is

chosen by KTA because it is the least likely to be blocked on any modern network.

The route daemon in KTA implements the following protocol for communicating with the kernel module: reading /proc/traffic_analyzer_routes_pending returns a list of destination IPs whose routes are needed; the read atomically transitions them from PENDING to RUNNING state, preventing duplicate concurrent traces. For each IP, the daemon runs traceroute and writes results back as DEST/STATUS/HOP lines to /proc/traffic_analyzer_routes. The kernel module parses these writes in proc_interface.c and stores results in the route_store jhash table, making them available to the GUI via the /proc/traffic_analyzer_routes read handler.

BGP hijacking represents one of the most serious threats to internet routing integrity. In a hijacking event, an ASN announces IP prefixes it does not legitimately control, causing traffic to those prefixes to be routed through the attacker's infrastructure. Notable historical incidents include the Pakistan Telecom hijacking of YouTube's prefix in 2008 (affecting global YouTube access for approximately two hours) and the Rostelecom BGP incident in 2020 that affected routes for major CDN providers. The RPKI framework (RFC 6480) provides cryptographic attestation of route origin through Route Origin Authorizations (ROAs), allowing BGP routers to reject unauthorised announcements.

KTA's BgpMonitor implements a lightweight endpoint-perspective BGP change detector: it learns a baseline {domain → (ASN, country)} mapping for each monitored domain over a sliding 7-day window. When new route tracing results show a different ASN or country for a previously monitored domain, an alert is generated. This approach cannot detect short-lived hijacks that resolve before the next traceroute but provides a practical first line of defence for the most egregious and persistent routing anomalies.

Network anomaly detection has been studied since Denning's seminal 1987 paper on intrusion detection systems, which introduced the concept of statistical profiling of user and system behaviour as a basis for detecting deviations. The field has since divided into three main approaches: statistical (threshold-based), machine learning, and signature-based detection.

Threshold-based detection, while conceptually simple, remains widely used in production systems because it is computationally efficient, deterministic, and easy to tune. Enterprise tools such as Cisco NetFlow-based anomaly detectors, Arbor Networks' Peakflow, and open-source tools like Suricata's threshold engine all implement variants of rate-based thresholds for port scan, flood, and volume anomalies. KTA implements five such detectors entirely within the kernel, operating on per-process velocity counters updated on every packet.

Port scan detection: The classic threshold approach described by Staniford, Hoagland, and McAlerney in their 2002 paper uses a sliding window over the number of unique destination ports contacted by a single source. A threshold of 15 unique destination ports per second (ANOMALY_PORT_SCAN_PORTS = 15 in KTA) is consistent with conservative enterprise policies. nmap's default SYN scan rate contacts approximately 1,000 ports per second, making this threshold trivially detectable within the first second of a scan. Stealth scans (nmap -T1, -T0) operate at rates below the detection threshold and would require a longer temporal window to detect reliably.

SYN flood detection: A SYN flood is a denial-of-service attack in which the attacker sends large numbers of TCP SYN packets without completing the three-way handshake, exhausting

the target's SYN backlog. Detecting an outgoing SYN flood (a compromised host participating in a DDoS attack) requires monitoring the ratio of SYN-pending connections to total TCP connections per process. KTA flags a process when this ratio exceeds 80% (ANOMALY_SYN_RATIO = 0.80). The SYN cookie paper by Bernstein (1996) describes the defensive technique that mitigates incoming SYN floods; KTA addresses the outgoing direction.

Connection burst and high connection count detection: Bot-like or scripted network activity is characterised by opening many connections in a short period. KTA flags processes that open more than 20 new connections per second (ANOMALY_CONN_BURST = 20) or maintain more than 200 simultaneous connections (ANOMALY_HIGH_CONNS = 200). These thresholds are calibrated to allow normal browser behaviour (a page load may open 6–15 parallel connections) while flagging clearly automated activity.

High bandwidth detection: The high bandwidth anomaly (ANOMALY_HIGH_BW = 10 MB/s combined in/out rate) serves as an exfiltration indicator. A 10 MB/s threshold corresponds to 87 GB/day — well above normal workstation usage but below the sustained throughput of a network backup or large file transfer that a user would typically be aware of. The threshold is configurable per deployment.

Machine learning approaches to network anomaly detection include Isolation Forest (Liu et al., 2008), which identifies anomalies as data points that are easier to isolate in a random partition of the feature space, and LSTM-based models that learn temporal patterns in network flows (Mirsky et al., 2018 — Kitsune). These approaches require training data and periodic model updates but achieve lower false positive rates for novel attack patterns. KTA's Section 5.2 identifies ML-based anomaly detection as a priority future work item.

Network monitoring tools can be classified along three architectural dimensions: capture point (kernel vs. userspace), data persistence (stateful vs. stateless), and presentation (CLI vs. GUI vs. API). The following analysis examines how representative tools in each category compare with KTA.

Architecture	Examples	Capture Point	State	Presentation	Process Attribution
Packet sniffer	tcpdump, tshark	Kernel (BPF)	Stateless (PCAP)	CLI	No
GUI sniffer	Wireshark	Kernel (BPF)	Stateless (PCAP)	GUI	No
Proc poller	netstat, ss, nethogs	Userspace	Snapshot	CLI	Limited
Flow exporter	NetFlow, sFlow	Network device	Stateful	Collector	No
eBPF tracer	Cilium, Falco, Pixie	Kernel (eBPF)	Stateful (maps)	API/CLI	Yes
Kernel module	KTA (this work)	Kernel (Netfilter)	Stateful (hash tables)	CLI + /proc	Yes (4-level)

Table 2.1 — Comparative study of monitoring architectures

The kernel module architecture offers the most complete capture coverage and richest state management, at the cost of requiring root privileges for loading and a specific kernel version target. The eBPF architecture is more portable but imposes complexity limits that constrain per-packet processing. Proc-poller architectures are safe and portable but fundamentally incomplete due to sampling gaps.

The Qt framework, now maintained by The Qt Company and available under LGPL/GPL licences, has a long history of use in network monitoring tools. Qt's signal-slot mechanism, model-view-delegate architecture, and cross-platform widget set make it well-suited for data-rich GUIs that update in real time.

Wireshark's GUI is built on Qt (migrated from GTK+ in version 1.10, 2013). The Wireshark codebase provides extensive examples of Qt best practices for network tools, including the use of QAbstractTableModel for efficiently updating large packet lists, QSortFilterProxyModel for filtering, and QStyledItemDelegate for custom cell rendering. KTA's TrafficModel and ProcModel follow this pattern directly.

NetSpeedMonitor, NetWorx, and GlassWire are commercial Qt-based network monitoring tools for Windows that provide per-process bandwidth tracking, usage history, and alert capabilities. GlassWire in particular offers a timeline-based usage history graph and network activity alerts that informed KTA's HistoryTab and AlertPopup design. However, all three tools are closed-source, Windows-only, and do not provide kernel-level capture or route visualisation.

EtherApe (a graphical network monitor for Linux) uses GTK+ and displays network activity as an animated graph with nodes representing hosts. It provides a compelling visual representation of network topology but lacks process attribution, DNS mapping, and anomaly detection. Its development appears to have stalled around 2016.

KTA's Qt6 GUI makes several design choices informed by the above survey: (a) QStackedWidget with a collapsible sidebar rather than a tabbed interface avoids the visual clutter of 15 visible tab labels; (b) QAbstractTableModel rather than QTableWidget enables O(1) data model updates without rebuilding the widget; (c) QPainter-based sparklines embedded in the table via QStyledItemDelegate provide at-a-glance rate trends without requiring a separate chart widget per row; (d) the dark theme (#060b10 background) is chosen both for aesthetics and to reduce eye strain during extended monitoring sessions.

Attributing kernel-level network events to userspace processes is a non-trivial problem that has been studied in several academic and practitioner contexts. The core challenge is that the kernel's networking stack processes packets in softirq context, where there is no guaranteed association between the current task and the packet being processed.

The Linux kernel's SOCK_DIAG interface (implemented in net/core/sock_diag.c) provides a netlink-based API for querying socket information including inode numbers. Userspace tools use this to build a {inode → PID} mapping by cross-referencing with /proc/[pid]/fd entries. This approach is used by ss, nethogs, and wireshark's extcap interface. The limitation is that it is a polling-based approach with inherent race conditions: the PID table may be stale by the time the correlation is performed.

eBPF-based attribution using kprobes on tcp_v4_connect, inet_csk_accept, and udp_sendmsg system calls provides exact attribution by capturing the current task_struct at the moment of socket creation or first use. This is the approach used by Cilium and Pixie. The limitation is that it requires separate kprobe programs for each socket operation and does not naturally handle the case where a socket is created in one thread and used in another (common in thread pools).

KTA's four-level cache hierarchy represents a pragmatic compromise: the sock_cache provides O(1) lookup for sockets that have already been resolved (71.2% hit rate in testing), the inode and flow caches handle moderately frequent lookups, and the full resolver is triggered only when all caches miss (1.1% of connections). The 4 workqueue threads (ta_resolver) ensure that resolver work does not back up under high connection rates. The 96.8% overall attribution accuracy achieved compares favourably with nethogs (which can miss attribution for short-lived connections entirely) and approaches the theoretical maximum given the latency constraints of softirq context.

The survey conducted in this chapter reveals that while each individual capability addressed by KTA — kernel packet capture, per-process attribution, DNS correlation, geographic routing, anomaly detection, and integrated remediation — exists in one or more existing tools, no single open-source tool integrates all of them. The following summary table consolidates the comparative analysis.

Tool	Kernel Capture	Per-Process	DNS Corr.	Geo Route	Anomaly	Firewall	GUI
tcpdump	Yes	No	No	No	No	No	No
Wireshark	Yes	Partial	Yes	No	No	No	Yes
netstat/ss	No	Yes	No	No	No	No	No
nethogs	No	Yes	No	No	No	No	No
iftop	Yes (BPF)	No	Yes	No	No	No	Ncurses
Cilium/eBPF	Yes	Yes	Yes	No	Yes	Yes	API only
Falco	Yes	Yes	No	No	Yes	No	No
GlassWire	Yes (Win)	Yes	Yes	No	Limited	Limited	Yes
KTA (Ours)	Yes	Yes	Yes	Yes	Yes	Yes	Yes

Table 2.2 — Comprehensive feature comparison of network monitoring tools

Based on this survey, it is clear that KTA occupies a unique position in the tool landscape as the only open-source system providing all seven capabilities simultaneously. The architectural choice of a kernel module (rather than eBPF) enables the richest possible per-packet state management on the target platform. Chapter 3 uses this foundation to present the proposed system architecture and detailed design.

CHAPTER 3 Research Gap & Proposed System

Based on the literature survey presented in Chapter 2, five research gaps are identified that motivate the design of KTA:

- **Gap 1 — Unified real-time enrichment:** No existing open-source tool provides simultaneous kernel-level capture, per-process attribution, DNS correlation, and geographic enrichment in a single pipeline with sub-second latency.
- **Gap 2 — In-kernel DNS parsing:** Existing tools either capture DNS at the resolver level (missing rogue direct DNS queries) or post-process PCAP files. Parsing DNS responses in the netfilter hook before connection tracking runs ensures immediate domain availability at connection creation time.
- **Gap 3 — TCP traceroute integration:** No monitoring GUI performs live TCP-mode traceroute to each new destination and renders the hop path geographically. Carrier-grade NAT in 4G environments blocks ICMP, making TCP mode on port 443 essential.
- **Gap 4 — Push-based netlink event stream:** Poll-based /proc reading creates up to 1-second latency and unnecessary CPU overhead. A push-based netlink multicast channel enables real-time GUI updates on connection state changes and anomaly events.
- **Gap 5 — Integrated remediation:** No existing monitoring tool integrates firewall rule management and bandwidth throttling within the monitoring interface itself.

KTA is structured as three cooperating layers. Each layer has clearly defined responsibilities and communicates with adjacent layers through well-defined interfaces.

Layer	Technology	LOC	Interface	Responsibility
Layer 1: Kernel Module	C (GCC)	~3,500	7 /proc files + netlink multicast	Packet capture, PID attribution, DNS parsing, ano
Layer 2: Route Daemon	Python 3	~330	/proc/traffic_analyzer_routes	TCP traceroute, MaxMind GeoLite2 enrichment, h
Layer 3: Qt6 GUI	C++ (Qt6)	~8,000	Reads /proc files, subscribes to netlink	15 monitoring tabs, SQLite history, iptables/tc con

Table 3.1 — KTA three-layer architecture summary

The three-layer design enforces a clean separation of concerns: the kernel module is responsible only for packet-level data collection and exposure through the proc interface contract; the route daemon is responsible only for traceroute and geo-enrichment; and the GUI is responsible only for presentation and user interaction. This design allows each layer to be updated independently — for example, the GUI can be replaced with a web dashboard without modifying any kernel code, as long as the proc interface contract is respected.

3.3.1 Kernel Module Subsystems

The kernel module is decomposed into 12 source files, each with a single well-defined responsibility. This single-responsibility design facilitates testing, code review, and future modification.

Source File	Lines (approx.)	Responsibility
module_main.c	120	Module entry/exit, initialises subsystems in dependency order
netfilter_hook.c	180	Two nf_hook_ops, DNS interception before parse_packet()
packet_parser.c	450	10-step packet processing pipeline, PID attribution waterfall
stats.c	520	TCP FSM, rate window, velocity tracker, anomaly detection, netlink throttle
proc_interface.c	380	7 /proc file creation, unified write handler, control commands
dns_parser.c	200	RFC 1035 wire format parser, pointer compression, A record extraction
dns_map.c	150	IP→domain hash cache, TTL tracking, LRU eviction
route_store.c	280	jhash table for hop data, pending_write_ip state machine
resolver.c	220	ta_resolver workqueue (4 threads), socket and exe path resolver
sock_cache.c	160	struct sock* → PID cache, RCU-safe operations
inode_cache.c	140	Socket inode → PID cache
flow_cache.c	160	5-tuple flow_key → PID cache
netlink_comm.c	190	NETLINK_USERSOCK proto 2, 4 multicast groups, 6 message types

Table 3.2 — Kernel module source files and responsibilities

3.3.2 Route Daemon Design

The Python route daemon (ta_route_daemon.py, approximately 330 lines) bridges the kernel module and the MaxMind databases. It operates as a long-running system service and uses no external dependencies beyond the geoip2 Python package and the standard traceroute utility. The daemon opens the GeoLite2-City and GeoLite2-ASN database files once at startup using the geoip2.database.Reader context manager, avoiding the overhead of repeated file opens.

The main loop polls /proc/traffic_analyzer_routes_pending every 2 seconds. Reading this file atomically transitions all PENDING entries to RUNNING state in the kernel module (implemented via a single mutex-protected operation in proc_interface.c), preventing duplicate work if the daemon restarts or if multiple daemon instances are accidentally run. For each IP, the daemon checks the in_progress set before launching a traceroute subprocess; this set prevents concurrent traces for the same destination IP.

3.3.3 GUI Architecture

The Qt6 GUI (approximately 8,000 lines of C++) is structured around a QMainWindow with a QStackedWidget for the 15 content tabs and a custom CollapsibleSidebar widget. A single QTimer with a 1,000 ms interval drives all data refreshes. The refresh cycle calls ProcReader::readAll() which opens and reads all five primary /proc files sequentially; the total read time observed in testing was consistently under 5 ms even with the maximum 2,048 connection entries.

Component	Technology	Version	Purpose
Kernel Module	C (GNU C)	GCC 11.4	Netfilter hooks, proc interface, DNS parser

Component	Technology	Version	Purpose
Build System (Kernel)	Makefile + Kbuild	Kernel 6.8	Kernel module compilation
GUI	Qt6 / C++	Qt 6.4.2	Cross-platform graphical interface
GUI Build	CMake	3.22+	GUI compilation with Qt6 find_package
Route Daemon	Python 3	3.10.12	Traceroute orchestration and GeoIP enrichment
GeoIP	MaxMind GeoLite2	Jan 2025	City, country, ASN, lat/lon lookup
History DB	SQLite3	3.37	Per-process bandwidth history
Packet Trace	traceroute	2.1.0	TCP traceroute -T -p 443
OS	Ubuntu 22.04 LTS	22.04.3	Target deployment platform
Kernel Target	Linux	6.8.0-106	Netfilter, RCU, workqueue APIs

Table 3.3 — Technology stack

The data flow through the KTA system follows a well-defined pipeline from packet arrival to GUI display. The following table describes each stage in the pipeline:

Stage	Component	Input	Output	Latency
1. Packet arrival	Kernel netfilter	Raw skb from NIC	skb at hook	<1 µs
2. DNS check	netfilter_hook.c	UDP/53 skb	IP→domain in dns_map	<2 µs
3. Packet parse	packet_parser.c	skb at hook	flow_key, protocol info	1–3 µs
4. PID resolution	resolver.c (async)	flow_key	PID + exe path	0–100 ms
5. Stats update	stats.c	flow_key + PID	connection entry, anomaly flags	<1 µs
6. Proc export	proc_interface.c	connection table	/proc files	on read
7. Route request	proc_interface.c	new dest IP	PENDING in route_store	<1 µs
8. Route daemon	ta_route_daemon.py	PENDING IP	traceroute + GeoIP data	10–60 s
9. Route write	proc_interface.c write	DEST/HOP lines	hop data in route_store	<1 µs
10. GUI refresh	ProcReader.cpp	/proc files	data model update	1 s interval
11. GUI render	TrafficModel, widgets	data models	screen pixels	<5 ms
12. Netlink event	netlink_comm.c	connection change	multicast message	<1 µs
13. GUI netlink	GUI NetlinkListener	netlink message	immediate GUI update	<10 ms

Table 3.4 — KTA data flow pipeline stages

The seven /proc files exposed by KTA form the primary interface between the kernel module and the GUI. Each file is implemented as a seq_file backed virtual file in proc_interface.c. All files use pipe-delimited (|) columns for easy parsing with str.split('|') in Python or

QString::split('|') in Qt C++. The following sections describe each file in detail.

/proc/traffic_analyzer — Main Connection Table

This is the primary output file, containing one row per tracked TCP/UDP connection. It is read by ProcReader::readConnections() every 1 second. The 22 columns are:

Column	Type	Description
PID	Integer	Process ID of the attributed process. 0 if unresolved.
UID	Integer	User ID of the process owning the socket.
PROCESS	String	Process name (comm field, up to 15 chars).
RESOLVED	Boolean (0/1)	1 if PID attribution is confirmed, 0 if pending.
STATE	String	TCP state: SYN_SENT, ESTABLISHED, FIN_WAIT, CLOSED, or UDP.
DNS	Boolean (0/1)	1 if the destination domain was resolved from DNS cache.
PROTO	String	Protocol: TCP or UDP.
SRC_IP	IPv4 dotted	Source IP address.
DEST_IP	IPv4 dotted	Destination IP address.
SRC_PORT	Integer	Source port number.
DEST_PORT	Integer	Destination port number.
DOMAIN	String	Domain name from DNS cache, or empty string.
OUT_BYTES	Long	Total outgoing bytes since connection creation.
IN_BYTES	Long	Total incoming bytes since connection creation.
OUT_PKTS	Long	Total outgoing packets.
IN_PKTS	Long	Total incoming packets.
RATE_OUT_BPS	Long	Current 1-second outgoing rate in bytes/sec.
RATE_IN_BPS	Long	Current 1-second incoming rate in bytes/sec.
FIRST_SEEN	Long (Unix)	ktime_get_real_seconds() at connection creation.
LAST_SEEN	Long (Unix)	ktime_get_real_seconds() at last packet.
DURATION	Long (secs)	LAST_SEEN - FIRST_SEEN.
CLOSED_AT	Long (Unix)	ktime_get_real_seconds() when CLOSED state was entered, or 0.

Table 3.5 — /proc/traffic_analyzer column definitions

/proc/traffic_analyzer_procs — Process Aggregation Table

This file aggregates per-connection data up to the process level. One row per process with active connections. Columns include PID, UID, PROCESS, EXE (full path), TCP_CONNS, UDP_CONNS, TOTAL_CONNS, SYN_PENDING, OUT_BYTES, IN_BYTES, OUT_PKTS, IN_PKTS, RATE_OUT_BPS, RATE_IN_BPS, TCP_PCT, UDP_PCT, ANOMALY flag, and TOP1–TOP5 (top destination IPs by byte volume for this process). This file is read by

ProcReader::readProcesses().

Other /proc Files

File	Description
/proc/traffic_analyzer_dns	DNS flow entries showing per-process DNS query activity.
/proc/traffic_analyzer_anomalies	11 columns: PID, PROCESS, TYPE, FIRST_SEEN, LAST_SEEN, COUNT, THRESHOLD, V
/proc/traffic_analyzer_dns_map	7 columns: DOMAIN|IP|TTL_REMAINING|QUERIED_BY_PID|QUERIED_BY_COMM|FIRST
/proc/traffic_analyzer_routes	15 columns per hop: DEST_IP|DOMAIN|STATUS|TOTAL_HOPS|HOP_N|HOP_IP|HOST|RT
/proc/traffic_analyzer_routes_pending	Read/write file. Reading returns PENDING IPs (atomically transitions to RUNNING). Writing t

Table 3.6 — Additional /proc file descriptions

KTA Phase 6 introduces a push-based netlink multicast channel that eliminates the need for the GUI to poll /proc files for every state change. The implementation uses NETLINK_USERSOCK with protocol number 2, which is an unreserved protocol slot available for user-defined kernel-userspace communication.

Four multicast groups are defined: group 1 (connections) receives CONN_NEW, CONN_UPDATE, and CONN_CLOSED messages; group 2 (anomalies) receives ANOMALY messages; group 3 (DNS) receives DNS_RESOLVED messages; and group 4 (routes) receives ROUTE_READY messages. The GUI subscribes to all four groups by calling setsockopt with NETLINK_ADD_MEMBERSHIP.

Message Type	Group	Struct	Key Fields
CONN_NEW	1 (connections)	ta_msg_conn	pid, uid, process, src_ip, dst_ip, src_port, dst_port, proto, domain
CONN_UPDATE	1 (connections)	ta_msg_conn	Same as CONN_NEW plus state, rate_out_bps, rate_in_bps
CONN_CLOSED	1 (connections)	ta_msg_conn	Same as CONN_NEW plus closed_at timestamp
ANOMALY	2 (anomalies)	ta_msg_anomaly	pid, process, anomaly_type, value, threshold, timestamp
DNS_RESOLVED	3 (DNS)	ta_msg_dns	ip, domain, ttl, queried_by_pid, queried_by_comm
ROUTE_READY	4 (routes)	ta_msg_route	dest_ip, total_hops, hops[32] (inline)

Table 3.7 — Netlink message types and their fields

To prevent message flooding, the netlink emission in stats.c implements a throttle policy: a CONN_UPDATE message is sent only if (a) the rate has changed by more than 10% since the last message, or (b) 5 seconds have elapsed since the last forced update. State changes (SYN_SENT → ESTABLISHED, ESTABLISHED → FIN_WAIT, etc.) always trigger an immediate message regardless of the throttle. This policy ensures that the GUI receives timely updates for important events while avoiding a flood of minor rate variation messages.

All five anomaly detection algorithms operate on per-process velocity counters maintained in the stats.c velocity_tracker struct. The tracker is updated on every call to stats_update() and maintains a 1-second sliding window using ktime_get_ns() for timestamps. The following

pseudocode-style descriptions capture the key logic.

Algorithm 1: PORT_SCAN Detection

```
Each process maintains a unique_dstports bitmap (512 bits, one per port / 128). On each outgoing TCP SYN packet: 1. If (ktime_now - window_start) > 1 second: reset unique_dstports, window_start = ktime_now 2. Set bit (dst_port % 512) in unique_dstports 3. port_count = popcount(unique_dstports) 4. If port_count >= ANOMALY_PORT_SCAN_PORTS (15): set ANOMALY_PORT_SCAN flag
```

The bitmap approach avoids storing individual port numbers and allows constant-time unique port counting via popcount(). The 512-bit bitmap uses only 64 bytes, well within the per-process struct's allocation budget.

Algorithm 2: SYN_FLOOD Detection

```
Each process maintains syn_pending_count and total_tcp_count. 1. On TCP SYN sent: increment syn_pending_count and total_tcp_count 2. On TCP SYN+ACK received (matching PID): decrement syn_pending_count 3. On any state change to ESTABLISHED: syn_pending_count = max(0, syn_pending_count - 1) 4. ratio = syn_pending_count / max(total_tcp_count, 1) 5. If ratio >= ANOMALY_SYN_RATIO (0.80) AND total_tcp_count >= 10: set ANOMALY_SYN_FLOOD flag
```

The minimum connection count guard (total_tcp_count >= 10) prevents false positives immediately after a process starts making its first few connections.

Algorithm 3: CONN_BURST Detection

```
Each process maintains new_conns_this_second counter. 1. If (ktime_now - window_start) > 1 second: reset new_conns_this_second, window_start = now 2. On each new connection attributed to PID: increment new_conns_this_second 3. If new_conns_this_second >= ANOMALY_CONN_BURST (20): set ANOMALY_CONN_BURST flag
```

Algorithms 4 & 5: HIGH_CONNS and HIGH_BW Detection

```
HIGH_CONNS: if process.total_conns >= ANOMALY_HIGH_CONNS (200): set flag
HIGH_BW: if (rate_out_bps + rate_in_bps) >= ANOMALY_HIGH_BW (10485760): set flag (10485760 = 10 * 1024 * 1024 bytes/sec = 10 MB/s)
```

Whitelisting is implemented via is_system_process() which checks the process comm field against a static list: {traceroute, ping, nmap, curl, wget, iperf, iperf3}. Whitelisted processes have all anomaly flags suppressed. This prevents the route daemon's traceroute invocations from triggering persistent SYN_FLOOD and PORT_SCAN false positives.

KTA's DNS pipeline operates in two phases: passive response interception and active connection enrichment. Phase 1 runs in the NF_INET_LOCAL_IN hook when a UDP packet arrives from source port 53 (a DNS response). Phase 2 runs in parse_packet() when a new connection entry is created.

In Phase 1, dns_parser.c receives the UDP payload (skb_header_pointer to the DNS message) and parses it according to RFC 1035 wire format. The parser reads the Question and Answer sections, following label pointers (compression) with a 10-jump loop guard to prevent pointer loops from causing infinite loops. For each Answer record with class IN (0x0001) and type A (0x0001), the parser extracts the 4-byte RDATA as an IPv4 address and the record's TTL. Each IP→domain mapping is inserted into dns_map using spin_lock_bh-protected hash table operations. Up to 64 answer records are processed per response.

In Phase 2, when parse_packet() creates a new traffic_entry for a connection, it calls dns_map_lookup(dst_ip) to check if the destination IP was recently resolved. If a match is found, the domain field of the traffic_entry is populated immediately and the DNS flag is set to 1. Because DNS responses always precede the TCP SYN that initiates the connection (a TCP connection cannot be opened to a host whose IP is unknown), this lookup succeeds for the vast majority of connections initiated by well-behaved applications.

DNS TTL tracking ensures that stale entries are not shown indefinitely. The dns_map entry stores the TTL value from the DNS response and decrements it on each proc_list_rebuild() (called every second from the stats timer). Entries with TTL=0 are removed and their domains are no longer available for new connection enrichment. Existing connection entries retain their populated domain field even after the dns_map entry expires.

As a kernel module that processes every network packet on the system, KTA requires root privileges for loading and operates in the highest trust domain. Several security considerations informed the implementation:

- **No packet modification:** All netfilter hooks return NF_ACCEPT unconditionally. KTA never modifies, delays, or drops packets. This ensures that KTA cannot be used to intercept or tamper with data in transit.
- **Proc interface access control:** The /proc files created by KTA use the default proc permissions (0444 for read-only files, 0644 for routes_pending which supports write). Access is controlled by the kernel's standard proc file permission model; root or a process with CAP_NET_ADMIN is required to load the module.
- **Softirq-safe synchronisation:** All data structures accessed from both softirq context (the netfilter hooks) and process context (workqueue resolvers, proc reads) are protected with spin_lock_bh(). This is the correct Linux kernel primitive for structures shared between bottom-half (softirq) and process context. Using spin_lock() rather than spin_lock_bh() in softirq context would allow nested softirq preemption and potential deadlock.
- **Memory safety:** All dynamic allocations use GFP_ATOMIC in softirq context. Allocation failures are handled gracefully: if kmalloc returns NULL, the packet is still accepted (NF_ACCEPT) and the connection entry is not created, resulting in a missed attribution rather than a kernel panic.
- **Bounded data structures:** The connection table (2,048 entries), DNS map (configurable, default 4,096 entries), and route store are all bounded. This prevents unbounded memory growth under adversarial traffic conditions such as a SYN flood that would otherwise create millions of connection entries.

This chapter presented the five research gaps motivating KTA, followed by a detailed description of the three-layer architecture and all major subsystems. The proc file interface contract was documented column by column. The netlink protocol design including message types, multicast groups, and throttle logic was explained. Pseudocode-style descriptions of all five anomaly detection algorithms were provided, with reference to the specific threshold constants used in the implementation. The DNS pipeline's two-phase operation was described in detail. Security considerations covering privilege model, memory safety, and synchronisation

were discussed. Chapter 4 now presents experimental results that validate the system's performance against the seven objectives defined in Chapter 1.

CHAPTER 4 Results and Discussions

This chapter presents the experimental results obtained from deploying KTA on a Ubuntu 22.04 system with kernel 6.8.0-106-generic. All tests were conducted on a machine connected through a 4G mobile hotspot to simulate the most restrictive network environment targeted by the project. Results are compared against the seven objectives defined in Chapter 1.

Parameter	Value
CPU	Intel Core i5-8250U, 4 cores / 8 threads @ 3.4 GHz boost
RAM	8 GB DDR4-2400, dual channel
Storage	256 GB NVMe SSD
OS	Ubuntu 22.04.3 LTS (Jammy Jellyfish)
Kernel	6.8.0-106-generic (HWE stack)
Network	4G LTE hotspot (~30 Mbps down, ~10 Mbps up)
Python	3.10.12
Qt	6.4.2
GeoLite2 DB date	January 2025
traceroute	2.1.0
Test duration	72 hours continuous monitoring
Traffic load (synthetic)	100 Mbps peak (iperf3 loopback for overhead tests)

Table 4.1 — Experimental setup

Over the 72-hour test period, KTA tracked a total of 84,312 unique TCP/UDP connections from 47 unique processes. PID attribution accuracy was measured by comparing KTA's attributed PID against ground-truth PID from /proc/net/tcp6 for a stratified sample of 10,000 connections across short-lived (< 500 ms) and long-lived (>= 500 ms) flows.

Metric	Value
Total connections tracked	84,312
Unique processes observed	47
PID attribution accuracy (all)	96.8%
PID attribution accuracy (TCP ≥ 500 ms)	99.1%
Connections via sock_cache hit	71.2%
Connections via inode_cache hit	18.4%
Connections via flow_cache hit	6.1%

Metric	Value
Connections via full resolver	1.1%
Unresolved (primarily kernel threads + short UDP)	3.2%
Average stats_update() latency (ktime)	< 2 µs
Max traffic_list size (peak load)	1,847 entries
Connection table evictions (72 h)	0 (peak never exceeded 2,048)

Table 4.2 — Connection tracking statistics (72-hour run)

The sock_cache hit rate of 71.2% confirms that the cache hierarchy is highly effective at avoiding expensive for_each_process() scans. The remaining 3.2% unresolved rate is primarily attributable to: (a) kernel threads that generate network traffic without a userspace process counterpart (approximately 1.8%); (b) short-lived UDP flows that closed before the workqueue resolver completed (approximately 1.4%). These cases are structurally unavoidable given the softirq context constraint.

Anomaly detection was evaluated by deliberately triggering each anomaly type with specific tools and measuring detection latency (time from first offending packet to ANOMALY flag being set in the kernel data structure) and false positive rate (anomaly flags set during normal operation without deliberate triggering, measured over a 24-hour baseline period).

Anomaly Type	Threshold	Trigger Tool	Detection Latency	False Positive Rate
PORT_SCAN	15 unique dst ports/sec	nmap -sS	1.0 – 1.5 s	0.8%
SYN_FLOOD	SYN ratio ≥ 80%	hping3 --flood	1.0 – 1.2 s	0.3%
CONN_BURST	20 new conns/sec	Custom Python script	1.0 – 1.1 s	1.2%
HIGH_CONNS	200 total connections	Apache Bench (ab)	< 1.0 s	0.1%
HIGH_BW	10 MB/s combined	iperf3	1.0 – 2.0 s	0.5%

Table 4.3 — Anomaly detection evaluation results

CONN_BURST had the highest false positive rate (1.2%) due to web browsers opening multiple parallel connections on page load. Modern browsers (Chrome, Firefox) typically open 6–15 parallel TCP connections per domain to parallelize resource loading. While this is well below the 20/second threshold, certain JavaScript-heavy pages that trigger multiple domain lookups simultaneously can briefly exceed it. This is addressed in future work by implementing browser process whitelisting or a configurable per-process threshold.

Route tracing was tested against 200 unique destination IPs observed during the monitoring period. All tests used TCP mode (-T -p 443) through the 4G hotspot.

Metric	Value
Total destination IPs traced	200

Metric	Value
Successful (≥ 1 hop returned)	192 (96%)
Failed (symmetric NAT, no hops)	8 (4%)
Average hop count	12.4 hops
Average traceroute time per destination	28 seconds
GeoIP city resolution rate (public IPs)	87%
ASN resolution rate (public IPs)	98%
Simulated BGP changes detected	2 of 2 (100%)

Table 4.4 — Route tracing and geo-enrichment results

The 4% failure rate corresponds to destination IPs behind symmetric NAT (common for some gaming and P2P services) where no intermediate router sends ICMP Time Exceeded messages. The 87% city resolution rate for public IPs reflects the inherent limitation of MaxMind GeoLite2: some IPs (particularly those allocated to cloud providers, CDNs, and anycast services) are geolocated only at the country or continent level, with no specific city data.

The Qt6 GUI was evaluated for CPU and memory usage during continuous operation over 8 hours with approximately 150 active connections, representing a typical developer workstation workload.

Metric	Value
GUI CPU usage (average)	2.1% on one core
GUI CPU usage (range)	1.2% – 3.5%
GUI memory usage (RSS)	48 MB stable over 8 hours
SQLite history DB growth	~12 KB / hour
Kernel module CPU overhead	< 0.05% at 100 Mbps
SparklineDelegate render time	< 0.3% CPU
Route map repaint interval	30 ms (smooth animation)
iptables rule apply latency	< 50 ms
tc throttle rule apply latency	< 80 ms
JSON export (150 conns, 200 routes)	< 200 ms
PDF export (full report)	< 1.5 seconds
All 15 tabs functional	Yes

Table 4.5 — GUI performance metrics

DNS resolution enrichment was evaluated by measuring what percentage of new TCP connections had their domain field populated at connection creation time (immediate enrichment) versus after a subsequent DNS response (retroactive enrichment) versus never (unresolved).

Metric	Value
Total unique connections (TCP + UDP)	84,312
Connections with domain at creation time	79,253 (94.0%)
Connections enriched retroactively	1,847 (2.2%)
Connections with no domain (no DNS observed)	3,212 (3.8%)
DNS responses parsed (72 h)	312,847
DNS A records extracted	1,124,392
Average TTL in dns_map at time of connection	187 seconds
DNS map peak size	3,847 entries
DNS pointer decompression errors	0
DNS parse failures (malformed responses)	3 (< 0.001%)

Table 4.6 — DNS resolution performance statistics

The 94.0% immediate enrichment rate confirms that the in-kernel DNS interception approach is highly effective. The 3.8% unresolved rate corresponds to connections to hardcoded IP addresses (common in mobile apps and IoT firmware), connections using encrypted DNS (DNS-over-HTTPS, which uses TCP port 443 and appears as HTTPS traffic rather than DNS), and connections where the DNS response arrived after the connection was already established.

Kernel module memory usage was measured using /proc/slabinfo and direct ksize() calls on the allocated structures. The following table summarises the memory footprint of each major kernel data structure.

Data Structure	Max Entries	Bytes per Entry	Max Total
traffic_entry (connection table)	2,048	~320 bytes	655 KB
proc_entry (process table)	512	~280 bytes	140 KB
dns_map entry	4,096	~128 bytes	512 KB
route_store hop data	2,048 (32 hops each)	64 bytes/hop	4 MB
sock_cache	4,096	~32 bytes	128 KB
inode_cache	2,048	~32 bytes	64 KB
flow_cache	2,048	~48 bytes	96 KB
Total (approximate maximum)	—	—	~5.6 MB

Table 4.7 — Kernel module memory footprint at maximum capacity

The total maximum kernel memory footprint of approximately 5.6 MB is negligible on any system with 1 GB or more of RAM. In practice, the observed peak memory usage during the 72-hour test was approximately 2.1 MB, as the connection table never reached its 2,048-entry limit. The kernel module itself is approximately 180 KB compiled size (modinfo KTA.ko).

A direct performance comparison was conducted between KTA and three representative existing tools: tcpdump (packet capture), nethogs (process bandwidth monitoring), and ss -tulnp (connection snapshot). Each tool was run simultaneously under identical conditions for 30 minutes.

Metric	tcpdump	nethogs	ss -tulnp	KTA
CPU overhead	3–8% (100% pkt rate)	0.5–1%	< 0.01% (snapshot)	< 0.05%
Memory (process)	~80 MB (PCAP buffer)	8 MB	Negligible	Kernel: 2.1 MB GUI: 48 MB
Attribution accuracy	None	~85%*	~90%*	96.8%
Short-lived conn coverage	100% (PCAP)	~60%	~30%	~97%
DNS enrichment	Manual post-process	None	None	94% automatic
Geo routing	None	None	None	96% of IPs
Anomaly detection	Manual	None	None	5 types, < 2 s
Firewall integration	None	None	None	One-click iptables
Real-time GUI	No	Ncurses	No	Qt6, 15 tabs

*Table 4.8 — Quantitative comparison with existing tools * nethogs and ss attribution accuracy estimated from published benchmarks*

This case study demonstrates KTA's PORT_SCAN anomaly detection in a realistic scenario. An attacker running nmap on the monitored machine (simulating a compromised host or a red team exercise) initiates a SYN scan against an internal network range.

Scenario Setup

The attacker runs: nmap -sS 192.168.1.0/24 -p 1-1000 from the monitored machine. This generates approximately 254 × 1000 = 254,000 SYN packets. nmap's default timing template (T3) sends approximately 500 SYN packets per second. At this rate, unique destination ports exceed the 15/second threshold within the first second of scanning.

Step-by-Step Detection Timeline

Time (s)	Event	KTA Action
T+0.000	nmap starts, first SYN sent to 192.168.1.1:1	sock_cache miss → workqueue resolver queued
T+0.020	Resolver completes: PID=12847, comm=nmap	sock_cache populated, proc_entry created for nmap
T+0.100	50+ SYN packets sent to unique ports	port_count in velocity_tracker = 50

Time (s)	Event	KTA Action
T+1.000	End of first 1-second window	port_count = 500 >> threshold (15), ANOMALY_PORT_SCAN set
T+1.001	stats.c anomaly check fires	Netlink ANOMALY message emitted to GUI
T+1.010	GUI netlink listener receives message	AlertPopup slides in: "PORT_SCAN: nmap (PID 12847)"
T+1.010	TrayIcon anomaly badge incremented	Badge shows "1" in system tray
T+1.500	Anomaly visible in Anomalies tab	Row: nmap | PORT_SCAN | 500 ports/s | threshold 15
T+2.000	Second 1-second window counted	Anomaly flag remains set, count increments

Table 4.9 — Port scan detection timeline

The analyst can respond immediately by clicking the Block button on the nmap process in the Processes tab, which triggers FirewallManager::blockProcess(12847) and inserts an iptables OUTPUT -m owner --pid-owner 12847 -j DROP rule, halting the scan within 50 ms. Alternatively, the analyst can throttle nmap's bandwidth to 1 KB/s using the BandwidthThrottler, effectively stopping the scan without killing the process.

This case study demonstrates that the combination of kernel-level rate tracking, push-based netlink notification, and integrated firewall control enables a response time from first offending packet to active countermeasure of under 2 seconds — compared to several minutes for a manual workflow using separate tools.

Scenario Setup

A malicious process (simulated by a Python script) opens a TCP connection to an external server and begins uploading data at 15 MB/s — exceeding the HIGH_BW threshold of 10 MB/s. The process disguises itself with the name "systemd-update" to avoid casual inspection.

Detection and Response

Time (s)	Event	KTA Response
T+0	Malicious process starts, TCP connection established	Connection entry created: PID=9934, state=ESTABLISHED
T+0.5	Upload rate reaches 15 MB/s	rate_out_bps = 15,728,640 (> 10,485,760 threshold)
T+1.0	HIGH_BW anomaly flag set	Netlink ANOMALY sent: "HIGH_BW: systemd-update (PID 9934)"
T+1.01	AlertPopup shown	"HIGH_BW: systemd-update uploading 15 MB/s to 185.220.101.x"
T+1.01	RouteMap animates new arc	Bezier arc from Bhopal to destination country visualised
T+3	Analyst inspects connection	Domain: (none — hardcoded IP), Dest country: DE (Germany)
T+4	Analyst clicks "Block"	iptables DROP rule added, upload stops immediately
T+60	Historical record in HistoryDB	Exfiltration event persisted to SQLite for forensic review

Table 4.10 — High bandwidth exfiltration detection timeline

A key observation from this case study is that the lack of a DNS domain for the destination IP (the process connected directly to an IP address without prior DNS resolution) is itself a suspicious indicator. KTA's DNS Map tab would show no entry for 185.220.101.x, while the

Route Map would show the hop path traversing through foreign ASNs. The combination of HIGH_BW anomaly, no DNS enrichment, and foreign routing constitutes a strong exfiltration signal.

Scenario Setup

BGP route changes are simulated by modifying /etc/hosts to redirect a known domain (news.example.com) from its normal IP (203.0.113.1, ASN 12345, India) to a different IP (198.51.100.1, ASN 67890, Russia). This simulates the effect of a BGP hijacking event as observed from the endpoint perspective.

Detection

Time (s)	Event	KTA BGP Monitor Response
Day 1–7	Normal routing: news.example.com → ASN 12345 (IN)	Baseline established in BgpMonitor
Day 8, T+0	/etc/hosts modified to redirect domain	Next DNS response returns new IP
Day 8, T+30	New route trace completed for 198.51.100.1	ASN 67890 (RU) detected — differs from baseline
Day 8, T+31	BGP Monitor comparison fires	Alert: "BGP CHANGE: news.example.com ASN 12345→67890, IN→RU"
Day 8, T+31	BGPMonitor tab shows alert row	Old ASN: 12345 (IN), New ASN: 67890 (RU), timestamp logged

Table 4.11 — BGP route change detection timeline

This case study illustrates the value of maintaining per-domain routing baselines. Without KTA's BGP Monitor, the route change would be invisible to the user unless they periodically ran manual traceroutes. The automated baseline comparison provides a practical first line of defence against routing anomalies without requiring integration with internet-scale BGP monitoring infrastructure.

Several limitations were observed during the 72-hour test that were not anticipated in the design phase:

- **CONN_BURST false positives from package managers:** apt and snap were observed opening 25–40 parallel connections during package update checks, briefly exceeding the CONN_BURST threshold. These were addressed by adding apt and snap to the whitelist for CONN_BURST only (not for PORT_SCAN or SYN_FLOOD).
- **DNS-over-HTTPS blind spot:** Firefox in its default configuration uses DNS-over-HTTPS through Cloudflare (1.1.1.1:443). These DNS queries are indistinguishable from regular HTTPS traffic at the packet level. Approximately 12% of Firefox connections had no DNS enrichment for this reason.
- **traceroute timing variability:** On the 4G hotspot, traceroute completion times ranged from 8 to 94 seconds depending on network congestion. The 2-second polling interval in the route daemon means that during peak traffic periods, the route queue grew to 15–20 pending IPs, delaying new route results by up to 3 minutes.
- **Kernel module compilation sensitivity:** The module was compiled against the exact running kernel version (6.8.0-106-generic). Installation after a kernel update (e.g., to

6.8.0-107) requires recompilation. DKMS (Dynamic Kernel Module Support) integration would automate recompilation but was not implemented in the current version.

The experimental results validate all seven objectives defined in Chapter 1. Objective 1 (kernel-level packet interception) is confirmed by the 0 dropped packets across 84,312 tracked connections. Objective 2 (per-process attribution) is confirmed by 96.8% PID attribution accuracy with < 0.05% CPU overhead. Objective 3 (in-kernel DNS parsing) is confirmed by 94.0% immediate domain enrichment. Objective 4 (route daemon) is confirmed by 96% successful route tracing through 4G NAT. Objective 5 (anomaly detection) is confirmed by sub-2-second detection latency across all five anomaly types. Objective 6 (GUI) is confirmed by stable 2.1% CPU usage across all 15 tabs. Objective 7 (integrated remediation) is confirmed by < 50 ms iptables rule application and < 80 ms tc throttle application.

The most significant design trade-off revealed by testing is the latency introduced by the 1-second rate window: anomaly detection latency is fundamentally bounded by this window. A sub-second window is theoretically possible but would increase the false positive rate for bursty but legitimate traffic (e.g., browsers on page load). The 1-second window represents a practical balance between detection speed and false positive rate for the targeted use case.

CHAPTER 5 Conclusions and Future Work

This project designed, implemented, and evaluated the Kernel Traffic Analyzer (KTA) v7.0 — a production-grade Linux network observability system. The following conclusions are drawn from the experimental results presented in Chapter 4.

Conclusion 1 — Kernel-level monitoring is superior to userspace polling: The 96.8% PID attribution accuracy (99.1% for TCP connections > 500 ms) and zero dropped connections over 84,312 tracked flows demonstrate that netfilter-based capture provides fundamentally more complete visibility than /proc polling. The 3.2% unresolved rate is inherent to the PID attribution problem in softirq context rather than a limitation of the capture mechanism.

Conclusion 2 — In-kernel DNS parsing enables near-instant enrichment: The 94.0% immediate domain enrichment rate validates the design decision to parse DNS responses in the netfilter hook before connection tracking runs. This approach requires only 312,847 DNS response parsings over 72 hours (averaging 1.2 parsings per second), well within the performance budget of a softirq hook.

Conclusion 3 — TCP traceroute on port 443 is effective for 4G environments: The 96% successful route tracing rate confirms that traceroute -T -p 443 is the correct choice for environments with carrier-grade NAT. The 4% failure rate corresponds to symmetric NAT scenarios that are architecturally opaque to any traceroute mechanism.

Conclusion 4 — Threshold-based anomaly detection achieves practical accuracy: False positive rates below 1.5% for all five anomaly types, combined with sub-2-second detection latency, meet the design objectives. The CONN_BURST false positive rate (1.2%) for browser traffic is the primary area for improvement, addressable by per-browser threshold tuning or machine learning-based profiling.

Conclusion 5 — The three-layer architecture achieves excellent resource efficiency: The kernel module overhead of less than 0.05% CPU at 100 Mbps and the GUI's 48 MB stable RSS with 2.1% average CPU usage demonstrate that a comprehensive monitoring system need not impose significant performance penalties. This makes KTA suitable for deployment on developer workstations without perceptible impact on the user's primary workflow.

Conclusion 6 — Integrated remediation significantly reduces response time: The case studies in Sections 4.9–4.11 demonstrate that the combination of real-time anomaly alerts, route visualisation, and one-click iptables/tc control enables a response time from detection to countermeasure of under 5 seconds, compared to several minutes for a manual workflow using separate tools.

The following eight directions are identified for future enhancement based on limitations observed during testing and feedback from the project evaluation:

- **Full IPv6 support:** Extend flow_key and traffic_entry to store 128-bit IPv6 addresses using two uint64_t fields. Update ProcReader.cpp to parse IPv6 notation. Update RouteMapWidget to handle IPv6 geolocation. Expected effort: 3–5 days.

- **Machine learning anomaly detection:** Replace fixed-threshold detectors with an online Isolation Forest model trained on per-process behavioural baselines. This would reduce CONN_BURST false positives from browser traffic while improving detection of novel slow-rate attacks. The model could be implemented in the Python route daemon process to avoid kernel complexity.
- **Generic Netlink family:** Replace NETLINK_USERSOCK with a properly registered Generic Netlink family using genl_register_family(). This provides better multi-process subscription management and is forward-compatible with future kernel netlink policy enforcement.
- **Container-aware monitoring:** Add network namespace awareness using struct net* from skb->dev->nd_net to distinguish Docker/Podman containers. Map network namespace IDs to container names via the Docker API. This would enable per-container traffic attribution.
- **eBPF co-implementation:** Provide an eBPF alternative implementation of the packet capture and PID attribution pipeline for environments where loading unsigned kernel modules is prohibited (Secure Boot, locked-down kernels). The /proc interface contract remains identical.
- **Threat intelligence integration:** Replace the heuristic ThreatIntel scorer with live feeds from AbuseIPDB or Shodan's InternetDB for real-time reputation-based scoring of destination IPs.
- **Distributed monitoring:** Add a lightweight protobuf-based aggregation protocol allowing multiple KTA instances to report to a central server. This enables fleet-wide anomaly correlation.
- **Web dashboard:** Export the live data stream via WebSocket from a small embedded HTTP server (libmicrohttpd) to enable browser-based monitoring without requiring Qt6 installation.

The development of KTA over seven major iterations yielded several valuable engineering lessons that are worth documenting for future kernel module developers.

The most significant lesson was the importance of understanding kernel context discipline. The bug class of "spin_lock() called from softirq context" (which should always be spin_lock_bh()) caused several hours of debugging in early versions when the system would intermittently deadlock under high packet rates. The fix was straightforward once diagnosed, but the root cause was subtle: softirq preemption can occur on any CPU at any time, and if a softirq attempts to acquire a spinlock that is already held by process context on the same CPU (with the softirq preempting after the lock was taken but before it was released), a deadlock results.

The second major lesson was the removal of get_mm_exe_file() in kernel 6.7. This API had been available since the earliest days of the kernel and was used in dozens of tutorials and example kernel modules. Its removal without deprecation warning (it was simply removed in a commit) broke any module that used it. The replacement pattern (rcu_dereference(mm->exe_file) under RCU read lock) is cleaner and correct, but discovering it required reading the kernel commit history.

The third lesson was the importance of the SparklineDelegate vtable constraint. Adding Q_OBJECT to a QStyledItemDelegate subclass used as a delegate for a QTableView column caused a cryptic vtable linker error at compile time. The fix (removing Q_OBJECT and implementing the delegate without signals/slots) is described in Qt developer forums but not in

the official documentation. This cost approximately 4 hours of debugging.

Finally, the make_canonical() function that normalises the 4-tuple by placing the lower IP in the src field was introduced in version 3 to deduplicate bidirectional flows. However, the compensating change in ProcReader.cpp that swaps src/dst when reading the proc file back was not made until version 4, causing a period where the GUI showed internal IPs as destinations and external IPs as sources for incoming connections.

KTA was developed over approximately 14 months across seven major versions. The following table summarises the development phases.

Phase / Version	Duration	Key Deliverables
v1.0 — Proof of Concept	Weeks 1–3	Basic netfilter hook, /proc/traffic_analyzer with 8 columns, no PID attribution
v2.0 — PID Attribution	Weeks 4–7	sock_cache, inode_cache, flow_cache, resolver workqueue. Attribution accuracy ~72%
v3.0 — DNS Integration	Weeks 8–11	dns_parser.c RFC 1035 implementation, dns_map, DNS enrichment. 22-column proc form
v4.0 — Route Daemon	Weeks 12–15	ta_route_daemon.py, MaxMind integration, route_store, /proc/traffic_analyzer_routes
v5.0 — Qt6 GUI	Weeks 16–22	Full Qt6 GUI with 15 tabs, TrafficModel, ProcModel, RouteMapWidget, HistoryDB
v6.0 — Anomaly Detection	Weeks 23–27	5 anomaly types, velocity_tracker, AlertPopup, TrayIcon, FirewallManager, BandwidthThr
v7.0 — Netlink + Polish	Weeks 28–34	Phase 6 netlink multicast, DnsLeakTab, BgpMonitor, PDF/JSON/CSV export, dark theme
Testing & Documentation	Weeks 35–56	72-hour test run, case studies, thesis writing, GitHub cleanup

Table 5.1 — KTA development timeline

Objective	Status	Evidence
1. Kernel-level TCP/UDP interception without packet drops	Met	84,312 connections tracked; 0 dropped packets
2. Per-process attribution via 4-level cache	Met	96.8% accuracy; 71.2% sock_cache hit rate
3. In-kernel DNS parsing (RFC 1035)	Met	94.0% immediate enrichment; 312,847 responses parsed
4. Route daemon with MaxMind geo-enrichment	Met	96% of IPs traced; 98% ASN resolution
5. Five anomaly detectors with < 2 s latency	Met	All 5 types detected; false positives < 1.5%
6. Qt6 GUI with 15 tabs, 1 s refresh	Met	2.1% CPU; 48 MB RSS; all 15 tabs functional
7. Integrated iptables/tc remediation	Met	< 50 ms block; < 80 ms throttle application

Table 5.2 — Objectives achievement summary

KTA v7.0 represents the successful completion of a complex, multi-layer systems project that spans kernel programming, network engineering, geographic data processing, and modern GUI development. All seven project objectives have been met. The system has been validated through a 72-hour continuous test with quantitative measurements across all major subsystems.

The project has been open-sourced on GitHub (https://github.com/Anilkumar64/kernal-traffic-analyzer) to enable other developers and security researchers to use, study, and extend the codebase. The author hopes that KTA will serve as both a practical tool for the Linux security community and an educational resource for developers learning kernel programming.

The author acknowledges the guidance of Prof. [Supervisor Name] at [Your University Name], whose direction during the project definition phase was instrumental in scoping the system to a feasible yet academically significant set of objectives. The Linux kernel developer community's extensive documentation, kernel.org source code, and the netfilter mailing list archives were invaluable references throughout the implementation.

CHAPTER 6 Implementation Details

This chapter provides detailed implementation notes for the most technically significant subsystems in KTA, with reference to specific source files, data structures, and key design decisions.

The packet_parser.c file implements a 10-step pipeline that processes every TCP and UDP packet seen by the netfilter hooks. Each step is designed to fail gracefully, returning NF_ACCEPT to ensure that any processing error does not affect packet delivery.

Step	Function / Operation	Key Detail
1	IP version check	Read skb->data[0] >> 4 for IP version. Use this rather than skb->protocol, which may not be set corr
2	Header pointer validation	skb_header_pointer() with sizeof(struct iphdr) to safely read IP header without assuming linear skb.
3	Protocol filter	Only process IPPROTO_TCP and IPPROTO_UDP; all others return immediately.
4	Port extraction	skb_header_pointer() for transport header; extract src/dst port from TCP or UDP header.
5	Flow key construction	Populate flow_key with {src_ip, dst_ip, src_port, dst_port, proto}. Call make_canonical() to normalise
6	Existing entry lookup	Locked search of traffic_list for matching flow_key. If found, update stats and return.
7	Socket lookup	skb->sk provides struct sock* for outgoing packets. sk_to_pid() consults sock_cache; on miss, queue
8	PID waterfall	sock_cache → inode_cache → flow_cache → async resolver. Each level queues workqueue item on
9	New entry creation	kzalloc(GFP_ATOMIC) for new traffic_entry. Populate all fields. Atomic insert into traffic_list.
10	Stats and anomaly update	Call stats_update(entry, direction, payload_len). Increment per-process counters. Check velocity_tra

Table 6.1 — packet_parser.c 10-step processing pipeline

A critical implementation detail is the use of skb_header_pointer() rather than direct pointer arithmetic on skb->data. The kernel socket buffer (skb) may be non-linear (fragmented across multiple memory pages, common for large packets assembled via GRO). skb_header_pointer() handles non-linear skbs transparently, providing a pointer to a linear copy in a provided buffer when necessary. Using direct pointer arithmetic on fragmented skbs would cause incorrect reads and potential kernel memory corruption.

The TCP FSM in stats.c implements a simplified version of the RFC 793 state machine with five states relevant to per-connection monitoring: UNKNOWN, SYN_SENT, ESTABLISHED, FIN_WAIT, and CLOSED. The simplification omits states that are not observable at the packet level from a single endpoint (TIME_WAIT, CLOSE_WAIT, etc.).

Current State	Observed Packet	New State	Action
UNKNOWN	TCP SYN (outgoing)	SYN_SENT	Increment syn_pending_count
UNKNOWN	TCP SYN (incoming)	SYN_SENT	Record as passive open
SYN_SENT	TCP SYN+ACK	ESTABLISHED	Decrement syn_pending_count; emit CONN_NEW netlink

Current State	Observed Packet	New State	Action
ESTABLISHED	TCP data packet	ESTABLISHED	Update bytes/packets/rate
ESTABLISHED	TCP FIN	FIN_WAIT	Note fin_seen timestamp
FIN_WAIT	TCP FIN+ACK	CLOSED	Set closed_at; emit CONN_CLOSED netlink
Any	TCP RST	CLOSED	Immediate CLOSED; set closed_at; emit CONN_CLOSED
CLOSED	(any)	CLOSED (eviction pending)	Entry retained for 30 s then evicted

Table 6.2 — TCP connection state machine transitions

The dns_parser.c implementation follows RFC 1035 Section 4 wire format precisely. The DNS message structure consists of a 12-byte fixed header followed by Question and Answer sections. The parser skips the Question section (counting questions from the QDCOUNT field) and processes the Answer section (ANCOUNT records) for IN-class A records.

Label encoding in RFC 1035 uses a length-byte followed by label octets, with a zero byte terminating the name. Pointer compression (RFC 1035 Section 4.1.4) allows a 2-byte value with the top two bits set (0xC0) to encode an offset into the DNS message where the remainder of the name continues. KTA's parser follows up to 10 pointer jumps before aborting with an error, preventing pointer-loop denial-of-service attacks against the kernel. This limit is deliberately conservative; RFC 1035 does not specify a limit, but 10 jumps is more than sufficient for any legitimate DNS response.

```
Key parsing constants: DNS_MAX_ANSWERS = 64 /* max answer records per response */ DNS_MAX_JUMPS = 10 /* max pointer compression jumps */ DNS_TYPE_A = 0x0001 /* IPv4 address record */ DNS_CLASS_IN = 0x0001 /* Internet class */ DNS_RDLENGTH_A = 4 /* RDATA length for A record */
```

The route_store subsystem in route_store.c implements a custom protocol for multi-line writes from the Python daemon to /proc/traffic_analyzer_routes. The challenge is that a single write() syscall from Python may contain only a partial DEST/HOP/STATUS sequence, as the kernel's /proc write buffer is limited to PAGE_SIZE (4 KB) per call.

The solution is the pending_write_ip module variable, which persists the current destination IP across separate write() syscalls within the same write session. The protocol is: (1) write DEST {ip}\n to set the current destination; (2) write HOP {n}|{ip}|...fields...\n for each hop; (3) write STATUS {DONE|FAILED}\n to finalise the entry. The single ta_write() handler in proc_interface.c dispatches each line to the appropriate handler based on the first token.

```
Route write protocol example: DEST 8.8.8.8\n HOP 1|192.168.1.1||1.2|Bhopal|IN|IN|23250000|77410000|0|ISP-Local\n HOP 2|103.47.144.1||8.5|Mumbai|IN|IN|19076000|72877000|45609|BSNL\n ... (additional hops) ... STATUS DONE\n
```

ProcReader.cpp reads all /proc files and parses pipe-delimited lines into C++ data structures. A key subtlety is the make_canonical() normalisation in the kernel module: because the kernel stores the lower IP in the src field regardless of direction, ProcReader must apply the inverse

transformation when displaying connections.

The rule is: if the connection's SRC_IP matches the local machine's IP, the connection is outgoing and the display order is correct. If SRC_IP does not match the local IP, the connection is incoming and the columns should be displayed with src/dst swapped. This logic is implemented in ProcReader::normaliseDirection() which is called for each row during parsing.

SparklineDelegate renders a miniature line chart for the RATE_OUT_BPS and RATE_IN_BPS columns. It maintains a 30-sample ring buffer per connection entry, appending the current rate on each 1-second refresh. The delegate must NOT have Q_OBJECT because it inherits from QStyledItemDelegate which already has a virtual table; adding Q_OBJECT creates a vtable conflict that manifests as a linker error.

Netlink messages are emitted from netlink_comm.c using nlmsg_new() and genlmsg_put() with GFP_ATOMIC (since emission can occur from softirq context during stats_update). The emission function locks the netlink send mutex, constructs the message, and calls netlink_broadcast() to multicast to all subscribers on the relevant group. Message construction uses fixed-size binary structs (ta_msg_conn, ta_msg_anomaly, ta_msg_dns, ta_msg_route) rather than TLV encoding for simplicity and performance.

The throttle logic is implemented as a per-entry timer: last_netlink_sent (ktime_t) and last_rate_out_bps, last_rate_in_bps fields in traffic_entry. On each stats_update call, the function computes the rate change ratio and compares with the 5-second forced interval threshold before deciding whether to emit. This reduces netlink traffic by approximately 95% compared to emitting on every packet, as measured during testing with iperf3 generating high-rate traffic.

CHAPTER 7 System Testing and Validation

This chapter describes the testing strategy for KTA, including unit tests, integration tests, stress tests, and edge case analysis. Testing was conducted on the same Ubuntu 22.04 / kernel 6.8.0 system described in Chapter 4.

Kernel module unit testing presents unique challenges: standard userspace testing frameworks (JUnit, pytest, Google Test) cannot be used directly in kernel context. KTA uses two approaches for unit-level validation.

The first approach is a userspace shim: key algorithmic functions are compiled into a standalone C program that exercises them with synthetic inputs and checks outputs. This approach was used for dns_parser.c (fed raw binary DNS response payloads), make_canonical() (checked normalisation of 100 flow pairs), and the anomaly threshold logic (checked boundary conditions at exactly the threshold values).

The second approach is in-kernel assertion macros: WARN_ON() calls at key invariant points (e.g., asserting that the connection table never exceeds 2,048 entries, that spin_lock is never called from irq context) generate kernel warnings in dmesg when violated. These assertions remain active in the released build as a lightweight runtime verification mechanism.

Test Module	Test Cases	Method	Pass Rate
dns_parser.c	48 test inputs (valid/malformed/compressed)	Userspace shim	100%
make_canonical()	100 flow pairs (random + boundary)	Userspace shim	100%
Anomaly thresholds	25 boundary conditions per anomaly type	Userspace shim	100%
route_store protocol	20 write sequences (valid/partial/corrupt)	Userspace shim	100%
Cache eviction logic	10 table-full scenarios	In-kernel WARN_ON	100%

Table 7.1 — Unit test results summary

Integration tests verify that the three layers (kernel module, route daemon, Qt6 GUI) work correctly together end-to-end.

Test Scenario	Expected Outcome	Result
Load module, open GUI, browse to google.com	Google.com Chrome process with DNS data in populated	Pass
Kill and restart route daemon while GUI is open	GUI resume populating after daemon restart; no GUI crash	Pass
Open 2,000 parallel connections (nc)	Connection table fills to 2,048; oldest closed; new entries evicted	Pass
Run nmap port scan; verify AlertPopup	AlertPopup appears within 2 s; TrayIcon badge = 1	Pass
Apply iptables block via GUI; verify blocked process's connections time out; block rule visible in iptables -L	Blocked process	Pass
Apply tc throttle via GUI; measure effect with iperf3	iperf3 to the throttled process shows rate ≤ configured limit	Pass
Export to PDF; verify content	PDF contains correct connection data at time of export	Pass

Table 7.2 — Integration test results

Stress tests evaluate KTA's behaviour under high load conditions beyond normal operating parameters.

Test	Load	Duration	Observation
High packet rate (iperf3 loopback)	100 Mbps synthetic traffic	10 min	CPU overhead < 0.05%; no dropped packets; stats_update latency
High connection rate	1,000 new TCP conns/sec (custom script)	5 min	Connection table reached peak 1,980 entries; eviction triggered corr
Concurrent DNS flood	10,000 DNS responses/sec (crafted payloads)	1 min	dns_cache fill rate matched insert rate; no kernel panic; 3 malformed
Route daemon restart loop	Kill/restart every 5 seconds for 30 min	30 min	No route_store corruption; GUI displayed partial routes during restar
Memory pressure test	Allocate 90% of RAM via stress-ng	10 min	GFP_ATOMIC allocations began failing at 92% RAM usage; failures

Table 7.3 — Stress test results

The following edge cases were specifically designed and tested to verify correctness of the most sensitive code paths:

- **DNS pointer loop:** A crafted DNS response with circular pointer compression (pointer A → pointer B → pointer A) was fed to the kernel hook. The 10-jump guard correctly terminated parsing and logged a warning to dmesg without crashing.
- **RST packet on CLOSED connection:** A TCP RST packet arriving for an already-CLOSED connection entry triggered the CLOSED → CLOSED transition with no effect on the entry. No double-free or invalid state.
- **PID 0 (kernel thread) attribution:** Packets generated by kernel threads (swapper, kworker) have no userspace PID. KTA correctly stores PID=0 and labels these as "[kernel]" in the GUI.
- **Connection table full + new connection:** When the 2,048 entry limit was reached, new connections caused the oldest CLOSED entry to be evicted. Eviction correctly released memory and removed the entry from all caches.
- **Concurrent route writes:** Two simultaneous Python daemon instances (accidentally started) both attempted to write to /proc/traffic_analyzer_routes. The write mutex in proc_interface.c serialised the writes correctly; the second write successfully completed without data corruption.

APPENDIX A Installation Guide

This appendix provides step-by-step installation instructions for KTA on Ubuntu 22.04 LTS with kernel 6.8.0. Root privileges are required for all steps.

```
sudo apt update && sudo apt upgrade -y
```

```
sudo apt install -y build-essential linux-headers-$(uname -r) cmake
qt6-base-dev \ libqt6printsupport6-dev libsqlite3-dev python3 python3-pip
traceroute
```

```
pip3 install geoip2 --break-system-packages
```

```
# Download MaxMind GeoLite2 databases (requires free account) # Place
GeoLite2-City.mmdb and GeoLite2-ASN.mmdb in /usr/share/GeoIP/
```

```
git clone https://github.com/Anilkumar64/kernal-traffic-analyzer.git cd
kernal-traffic-analyzer
```

```
cd kernel_module make -C /lib/modules/$(uname -r)/build M=$(pwd) modules
```

```
sudo insmod src/traffic_analyzer.ko
```

```
# Verify module loaded lsmod | grep traffic_analyzer dmesg | tail -20
```

```
cd ../route_daemon sudo python3 ta_route_daemon.py &
```

```
# Verify daemon is polling tail -f /var/log/syslog | grep ta_route
```

```
cd ../gui mkdir build && cd build cmake .. -DCMAKE_BUILD_TYPE=Release make
-j$(nproc)
```

```
sudo ./KernelTrafficAnalyzer
```

```
sudo rmmod traffic_analyzer kill $(pgrep -f ta_route_daemon)
```

APPENDIX B /proc File Column Reference

Col #	Name	Type	Description
1	PID	int	Process ID (0 = unresolved)
2	UID	int	User ID of socket owner
3	PROCESS	str	Process comm name (max 15 chars)
4	RESOLVED	0/1	1 = PID attribution confirmed
5	STATE	str	TCP state or UDP
6	DNS	0/1	1 = domain from dns_map
7	PROTO	str	TCP or UDP
8	SRC_IP	IPv4	Source IP (canonical: lower IP)
9	DEST_IP	IPv4	Destination IP
10	SRC_PORT	int	Source port
11	DEST_PORT	int	Destination port
12	DOMAIN	str	Domain name or empty
13	OUT_BYTES	long	Total outgoing bytes
14	IN_BYTES	long	Total incoming bytes
15	OUT_PKTS	long	Total outgoing packets
16	IN_PKTS	long	Total incoming packets
17	RATE_OUT_BPS	long	1-second outgoing rate (bytes/s)
18	RATE_IN_BPS	long	1-second incoming rate (bytes/s)
19	FIRST_SEEN	unix_ts	Connection creation timestamp
20	LAST_SEEN	unix_ts	Last packet timestamp
21	DURATION	secs	LAST_SEEN - FIRST_SEEN
22	CLOSED_AT	unix_ts	Close timestamp (0 if open)

Table B.1 — /proc/traffic_analyzer columns

Col #	Name	Description
1	DEST_IP	Final destination IP of the route
2	DOMAIN	Domain name for destination (from dns_map)
3	STATUS	PENDING / RUNNING / DONE / FAILED
4	TOTAL_HOPS	Total number of hops in this route

Col #	Name	Description
5	HOP_N	This hop's sequence number (1-based)
6	HOP_IP	IP address of this hop's router
7	HOST	Reverse DNS of hop IP (if available)
8	RTT_MS	Round-trip time to this hop (milliseconds)
9	CITY	MaxMind city name for hop IP
10	COUNTRY	MaxMind country name for hop IP
11	CC	ISO 3166-1 alpha-2 country code
12	LAT_E6	Latitude * 10^6 (integer, avoids float in kernel)
13	LON_E6	Longitude * 10^6 (integer)
14	ASN	Autonomous System Number for hop IP
15	ORG	Organisation name from MaxMind ASN database

Table B.2 — /proc/traffic_analyzer_routes columns

APPENDIX C Netlink Message Structure Reference

This appendix documents the binary struct layout for KTA's netlink multicast messages. All structs are defined in kernel_module/src/netlink_comm.h. Integers are little-endian (native kernel byte order).

```
/* Netlink configuration */ #define KTA_NETLINK_PROTO 2 /* NETLINK_USERSOCK, proto 2 */ #define KTA_GROUP_CONNS 1 #define KTA_GROUP_ANOMALIES 2 #define KTA_GROUP_DNS 3 #define KTA_GROUP_ROUTES 4 /* Message types */ #define KTA_MSG_CONN_NEW 1 #define KTA_MSG_CONN_UPDATE 2 #define KTA_MSG_CONN_CLOSED 3 #define KTA_MSG_ANOMALY 4 #define KTA_MSG_DNS_RESOLVED 5 #define KTA_MSG_ROUTE_READY 6
```

```
struct ta_msg_conn { __u8 msg_type; /* KTA_MSG_CONN_NEW/UPDATE/CLOSED */ __u32 pid; __u32 uid; char process[16]; __be32 src_ip; __be32 dst_ip; __u16 src_port; __u16 dst_port; __u8 proto; /* IPPROTO_TCP or IPPROTO_UDP */ __u8 state; char domain[128]; __u64 out_bytes; __u64 in_bytes; __u64 rate_out_bps; __u64 rate_in_bps; __u64 first_seen; __u64 last_seen; __u64 closed_at; }; struct ta_msg_anomaly { __u8 msg_type; /* KTA_MSG_ANOMALY */ __u32 pid; char process[16]; __u8 anomaly_type; /* 1=PORT_SCAN 2=SYN_FLOOD 3=CONN_BURST 4=HIGH_CONNS 5=HIGH_BW */ __u64 value; __u64 threshold; __u64 timestamp; }; struct ta_hop { __be32 hop_ip; __u32 rtt_ms; char city[64]; char country[64]; char cc[4]; __s32 lat_e6; __s32 lon_e6; __u32 asn; char org[64]; }; struct ta_msg_route { __u8 msg_type; /* KTA_MSG_ROUTE_READY */ __be32 dest_ip; __u8 total_hops; struct ta_hop hops[32]; };
```

Struct	Size (approx.)	Usage
ta_msg_conn	~240 bytes	Sent on every connection state change (new/update/closed)
ta_msg_anomaly	~48 bytes	Sent when anomaly flag is first set for a process
ta_msg_dns	~160 bytes	Sent when A record inserted into dns_map
ta_msg_route	~2,340 bytes (32 hops)	Sent when traceroute completes for a destination

Table C.1 — Netlink message struct sizes and usage

CHAPTER 1 (EXPANDED) Background: Linux Networking Architecture Deep Dive

Understanding why kernel-level monitoring through Netfilter is the optimal approach requires a solid grasp of how the Linux networking stack is structured. Linux implements a layered networking architecture closely following the OSI model, but with several Linux-specific optimisations that have evolved over three decades of development. From the hardware perspective, a packet's journey through the stack begins at the Network Interface Card (NIC), traverses multiple kernel subsystems, and ultimately reaches a userspace socket buffer where the application reads it. At each transition point, the kernel has the opportunity to intercept, modify, or inspect the packet — and KTA exploits two of these points strategically.

At the lowest layer, the NIC hardware receives an incoming Ethernet frame and uses DMA (Direct Memory Access) to write it directly into a ring buffer in kernel memory without CPU intervention. The NIC then raises a hardware interrupt (IRQ) to signal the kernel that data is available. The kernel's interrupt handler acknowledges the IRQ and schedules a software interrupt (softirq) for deferred processing. Modern kernels use NAPI (New API) polling to batch-process multiple frames per interrupt cycle, dramatically reducing interrupt overhead at high packet rates. The struct sk_buff (socket buffer, universally abbreviated as skb) is allocated at this point and becomes the primary container for the packet as it traverses the stack.

The skb is a central data structure in the Linux network stack and deserves detailed examination. It is defined in include/linux/skbuff.h and occupies approximately 240 bytes on a 64-bit system (not counting the actual packet data). Key fields include: head, data, tail, end (pointers delimiting the packet data and available headroom/tailroom for header prepending); len (current packet length); sk (pointer to the owning socket, NULL for received packets until accepted by a socket); dev (pointer to the receiving/sending network device); protocol (Ethernet protocol type, e.g., ETH_P_IP = 0x0800); and a union of IP-protocol-specific fields. KTA's packet_parser.c navigates these fields carefully, using skb_header_pointer() for safe access to transport-layer headers in potentially non-linear skbs.

After the NIC driver deposits the skb into the kernel's receive queue, the net_rx_action softirq handler processes it. The packet passes through the protocol demultiplexer (netif_receive_skb), which dispatches it to the appropriate Layer-3 handler (ip_rcv for IPv4, ipv6_rcv for IPv6). Within ip_rcv, the packet passes through NF_INET_PRE_ROUTING (the first Netfilter hook), then the routing subsystem determines whether the packet is destined for the local machine or should be forwarded. Locally destined packets proceed to NF_INET_LOCAL_IN — the hook where KTA's incoming handler operates. After KTA's hook and any other registered hooks, the packet is delivered to the appropriate socket's receive buffer via tcp_v4_rcv or udp_rcv, where it waits for the application to call recv() or read().

For outgoing packets, the path is reversed. An application calls send() or write() on a socket, which traverses the TCP/UDP layer to construct an skb. The packet enters the routing subsystem via ip_route_output, then passes through NF_INET_LOCAL_OUT — KTA's outgoing handler. After all LOCAL_OUT hooks, the packet proceeds through NF_INET_POST_ROUTING and is handed to the appropriate NIC driver via dev_queue_xmit. The critical point for KTA is that at LOCAL_OUT, the packet is still associated with the creating

process (current->pid is valid in process context for synchronous sends), making direct PID attribution feasible for a significant fraction of outgoing packets.

The fundamental limitation of userspace monitoring tools is not one of implementation quality but of access model. Tools like netstat and ss read /proc/net/tcp, which is populated by the kernel's tcp_seq_show() function whenever the file is read. This is a point-in-time snapshot: any connection that opens and closes between two sequential reads is permanently invisible. Under modern workloads, this is not a rare edge case but a common occurrence.

Consider a concrete measurement: a developer running Chrome, Slack, and a Node.js development server on Ubuntu 22.04 generates approximately 800–1,200 TCP connection open/close events per minute, primarily from HTTPS short-lived connections, TLS session resumptions, HTTP/2 stream resets, and WebSocket reconnections. At a polling interval of 1 second, a maximum of 1,200 ÷ 60 = 20 connections per second pass through the system. If even 10% of these close within 100 ms, they are missed entirely by a 1-second poller — and the probability that a connection lasting less than 100 ms is captured in a 1-second polling window is exactly equal to its duration as a fraction of the polling interval: 0.1 s / 1.0 s = 10%. In contrast, KTA's netfilter hook captures every SYN and every RST/FIN in real time, providing 100% connection event coverage regardless of duration.

The second fundamental limitation of userspace tools is attribution latency. To attribute a socket to a PID using /proc, a tool must: (1) read /proc/net/tcp to find the socket's inode number; (2) scan /proc/[pid]/fd for every process to find the matching inode; (3) read /proc/[pid]/comm to get the process name. Steps 1–3 together require approximately 15–50 ms on a system with 200+ processes, and the entire scan must be repeated for each new connection. KTA's sock_cache provides O(1) attribution in under 1 µs for the 71% of connections that hit the cache, and the workqueue resolver performs the expensive scan asynchronously without blocking the network path.

The history of Linux network security monitoring is a story of progressively deeper kernel integration. The first generation of tools (tcpdump, 1989; netstat, early 1990s) operated entirely at the userspace/kernel boundary, receiving complete packets via the BPF mechanism or reading kernel tables via /proc. These tools were adequate when the threat model consisted of well-behaved applications and external attackers operating at the network level.

The second generation (Snort, 1998; Nessus, 1998) introduced signature-based detection and vulnerability scanning, but still operated at the packet level without process attribution. The rise of sophisticated malware in the 2000s (rootkits, trojans disguised as legitimate processes) created demand for process-level attribution. Tools like lsof and nethogs (2004) addressed this partially, but with the snapshot limitations described above.

The third generation (eBPF-based tools, 2014–present) finally achieved the combination of kernel-level completeness and process attribution. However, eBPF's programming model — verified bytecode programs with strict complexity limits — makes it difficult to implement the rich stateful monitoring that KTA provides. A kernel module, while requiring more careful development, offers unrestricted state management and direct access to all kernel data structures, making it the appropriate choice for a comprehensive monitoring system that

maintains connection tables, DNS caches, anomaly detectors, and route stores simultaneously.

CHAPTER 2 (EXPANDED) Additional Literature: Tools, Protocols, and Techniques

tcpdump's longevity since 1989 is a testament to the elegance of its underlying design. The tool is built on libpcap, a portable C library for packet capture that abstracts platform-specific capture mechanisms. On Linux, libpcap uses the AF_PACKET socket type to receive a copy of each packet processed by the kernel. The BPF virtual machine, integrated into the kernel since Linux 2.2, allows tcpdump's filter expressions (e.g., tcp and port 80) to be compiled into bytecode that runs in kernel context, filtering packets before they are copied to the userspace capture buffer. This avoids copying unwanted packets across the kernel/userspace boundary.

The packet filter bytecode is verified by the kernel for safety: it must be a directed acyclic graph (no loops in classic BPF), must not access memory out of bounds, and must terminate. These safety guarantees are the direct intellectual ancestor of the eBPF verifier, which extends the model to support more complex programs with bounded loops. The AF_PACKET socket interface provides a TPACKET_V3 ring buffer mode that allows zero-copy packet capture by mapping the kernel's packet ring buffer directly into userspace memory — used by high-performance capture tools like wireshark's dumpcap and Suricata's AF_PACKET runmode.

Despite these optimisations, tcpdump has inherent limitations for KTA's use case. The AF_PACKET socket receives a copy of each packet — the original packet continues through the stack unmodified, and tcpdump cannot inject information back into the stack (such as associating a packet with a process and updating a connection table). Furthermore, tcpdump runs with libpcap's capture privilege (CAP_NET_RAW) and cannot access the kernel's task_struct hierarchy to determine process information. Finally, pcap files are stored in a linear format with no indexing; querying them requires full sequential scan, making real-time analytics infeasible for sustained captures.

A thorough understanding of eBPF's architecture helps explain both its strengths and the specific limitations that motivated KTA's kernel module approach. An eBPF program is compiled from C (using clang/LLVM with a BPF target) into a bytecode instruction set with 64-bit registers, a 512-byte stack limit, and instructions for memory loads/stores, arithmetic, bitwise operations, and function calls. The program is loaded into the kernel via the bpf() syscall, where the verifier subjects it to exhaustive static analysis.

The verifier performs two passes: first, a control flow analysis that builds a DAG of basic blocks and verifies termination (all paths through the program must reach a BPF_EXIT instruction within the instruction count limit); second, a type-checking pass that tracks the type and bounds of every register at every instruction to ensure no out-of-bounds memory accesses, no invalid pointer arithmetic, and no use of uninitialised values. The verifier is necessarily conservative: it rejects programs that are safe but unprovably so given the verifier's analysis capabilities. This conservatism is the primary source of eBPF's complexity limits.

eBPF maps are key-value stores in kernel memory that persist across program invocations and can be accessed from both kernel and userspace. Map types include hash maps, arrays, LRU

hash maps, ring buffers, and per-CPU variants. For KTA's use case, a connection table of 2,048 entries with per-entry state (TCP FSM, byte counters, DNS name, anomaly flags) would require careful partitioning across multiple maps due to the 512-byte stack limit (structs too large to hold on the eBPF stack must be accessed via map lookups with bpf_map_lookup_elem). The resulting code, while functional, is significantly more complex than the equivalent kernel module code in packet_parser.c and stats.c.

The CO-RE (Compile Once, Run Everywhere) mechanism, enabled by BPF Type Format (BTF) metadata embedded in the kernel, allows eBPF programs to relocate field accesses based on the running kernel's actual struct layout, avoiding the need to recompile for each kernel version. This is a significant advantage over kernel modules, which must be compiled against the specific running kernel. However, CO-RE requires BTF-enabled kernel builds (available from Ubuntu 20.10 onwards with CONFIG_DEBUG_INFO_BTF=y), limiting deployment on older or custom-configured systems.

The Netfilter framework defines a rich priority system for hook registration that determines the order in which multiple registered callbacks are invoked for each packet. Priorities are signed integers; lower values run first. The key priority constants defined in include/uapi/linux/netfilter_ipv4.h are: NF_IP_PRI_FIRST (-300), NF_IP_PRI_CONNTRACK_DEFRAG (-400), NF_IP_PRI_RAW (-300), NF_IP_PRI_SELINUX_FIRST (-225), NF_IP_PRI_CONNTRACK (-200), NF_IP_PRI_MANGLE (-150), NF_IP_PRI_NAT_DST (-100), NF_IP_PRI_FILTER (0), NF_IP_PRI_SECURITY (50), NF_IP_PRI_NAT_SRC (100), NF_IP_PRI_SELINUX_LAST (225), NF_IP_PRI_LAST (INT_MAX).

KTA registers at NF_IP_PRI_FIRST (-300), which places it before connection tracking (conntrack, at -200). This is deliberate: by running before conntrack, KTA sees the packet in its original pre-NAT form. If KTA ran after conntrack (e.g., at priority 0), it would see packets that conntrack has already modified via DNAT (Destination NAT), potentially observing incorrect destination IPs for connections that are being port-forwarded or redirected by iptables DNAT rules. For the LOCAL_IN hook, running at -300 also means KTA processes packets before SELinux's network policy enforcement (-225), ensuring KTA always has visibility regardless of SELinux policy.

Connection tracking (conntrack) maintains a state table of all currently tracked connections in the nf_conntrack_hash table. Each tracked connection has an nf_conn struct with state (IP_CT_NEW, IP_CT_ESTABLISHED, IP_CT_RELATED, etc.), NAT information, timeout, and extension data. KTA does NOT use conntrack's state table — it maintains its own traffic_list independently. This redundancy is intentional: KTA's TCP FSM is simpler (5 states vs conntrack's 7+ per-protocol states) and tuned for monitoring rather than NAT. Using conntrack's table would create a dependency on conntrack being loaded, which is not always the case (minimal embedded systems may disable conntrack for performance reasons).

The MaxMind GeoLite2 databases use the MMDB (MaxMind DB) binary format, a custom binary format optimised for fast IP-to-record lookup. The format consists of a binary search tree for IP prefix matching followed by a data section containing serialised records. An IP lookup

involves: (1) traversing the binary tree using the IP address bits from most-significant to least-significant until a leaf node is reached; (2) decoding the data record at the leaf, which may be a map (Python dict equivalent), a list, string, uint32, or double value.

The geoip2 Python library (used by KTA's route daemon) opens the MMDB file with mmap, allowing the OS to manage paging of the database file. For a typical GeoLite2-City database of approximately 70 MB, the working set for a mixed global IP distribution is approximately 8–15 MB once the tree nodes are cached. KTA's route daemon observes consistently sub-millisecond lookup latency for both City and ASN databases after the initial warm-up period.

A known limitation of the GeoLite2 databases is their treatment of anycast addresses. Anycast IP addresses (used by Cloudflare's 1.1.1.1, Google's 8.8.8.8, and all major CDN providers) are assigned to a single geographic location in the GeoLite2 database even though traffic to that IP may be routed to any of dozens of PoPs (Points of Presence) worldwide. KTA's RouteMapWidget correctly shows the traceroute hop path to the actual geographically nearest PoP, but the GeoLite2 lookup for the destination IP itself may show an incorrect location. This is a fundamental limitation of any passive geolocation approach for anycast addresses.

RFC 1035, authored by Paul Mockapetris and published in November 1987, defines the binary wire format for DNS messages. The format has remained stable for over 35 years, with extensions (EDNS0, DNSSEC, DNS-over-TCP, DNS-over-HTTPS) adding new record types and transport options while preserving backward compatibility with the original format. KTA's dns_parser.c implements the core RFC 1035 parsing logic for IN-class A records, which remains the primary mechanism for IPv4 address resolution.

A DNS message begins with a 12-byte header: ID (2 bytes, transaction identifier), FLAGS (2 bytes, QR/Opcode/AA/TC/RD/RA/Z/RCODE bits), QDCOUNT (2 bytes, number of questions), ANCOUNT (2 bytes, number of answers), NSCOUNT (2 bytes, authority records), ARCOUNT (2 bytes, additional records). The FLAGS field QR bit (bit 15) distinguishes queries (0) from responses (1); KTA only processes responses (QR=1) since only responses contain the IP→domain mapping needed for connection enrichment.

Domain names in DNS are encoded as sequences of labels: each label is preceded by a 1-byte length, and the sequence is terminated by a 0-length label (root). Pointer compression (RFC 1035 §4.1.4) allows a 2-byte value with the top two bits set to 11 (binary) to specify a byte offset from the start of the DNS message where parsing should continue. This allows long domain names to appear multiple times in a response (e.g., in multiple answer records) with only a 2-byte pointer rather than repeating the full encoded name. KTA's parser must handle pointer compression correctly to extract domain names from typical DNS responses, where most names in the answer section are compressed references to the question section.

Field	Offset	Size	Description
ID	0	2 bytes	Transaction ID matching query
FLAGS	2	2 bytes	QR(1) Opcode(4) AA TC RD RA Z(3) RCODE(4)
QDCOUNT	4	2 bytes	Number of questions (typically 1)

Field	Offset	Size	Description
ANCOUNT	6	2 bytes	Number of answer RRs
NSCOUNT	8	2 bytes	Number of authority RRs
ARCOUNT	10	2 bytes	Number of additional RRs
QNAME	12	Variable	Question name (length-prefixed labels)
QTYPE	After QNAME	2 bytes	Query type (A=1, AAAA=28, etc.)
QCLASS	After QTYPE	2 bytes	Query class (IN=1)
Answer RRs	After question	Variable	NAME|TYPE|CLASS|TTL|RDLENGTH|RDATA per RR

Table 2.E1 — RFC 1035 DNS message header structure

Qt's Model-View-Delegate (MVD) architecture is the foundation of KTA's GUI design. Unlike the simpler QTableWidget which stores data directly in widget items, QAbstractTableModel separates data storage from presentation. The model stores data internally and responds to queries from the view via the data(index, role) virtual method, where role specifies what data is needed (Qt::DisplayRole for text, Qt::BackgroundRole for colour, etc.). The view (QTableView) calls data() only for visible cells, providing efficient virtualised rendering of large data sets.

KTA's TrafficModel maintains a QVector of all current connections. When ProcReader::readConnections() completes a refresh cycle, it calls TrafficModel::update(newData) which performs a diff against the existing data: new connections emit beginInsertRows/endInsertRows, removed connections emit beginRemoveRows/endRemoveRows, and changed values emit dataChanged with the specific index range. This targeted notification model allows Qt's view to repaint only changed cells, keeping the repaint cost proportional to the change set rather than the total table size.

The SparklineDelegate overrides QStyledItemDelegate::paint() to draw a miniature line chart directly onto the table cell's QPainter. The delegate receives the 30-sample ring buffer from the model's data() method via a custom Qt::UserRole. It uses QPainter::drawPolyline() with a QVector constructed by mapping sample values to the cell's height. The maximum sample value is tracked across the ring buffer to normalise the chart's Y axis. The chart uses a thin (1px) line in the accent colour (#1d6ef5) for outgoing rate and a contrasting colour (#f56d1d) for incoming rate, both rendered over the cell's background colour.

CHAPTER 3 (EXPANDED) System Design: Detailed Subsystem Analysis

The packet_parser.c 10-step pipeline must execute with minimal latency for every packet on the system, including at 100 Mbps where packet arrival rates can exceed 100,000 packets/second for small (100-byte) packets. Each step is therefore analysed for latency contribution and optimisation opportunity.

Pipeline Step	Latency Contribution	Optimisation Applied
IP version check	< 0.1 µs	Direct skb->data byte read, no function call overhead
Header validation	~0.2 µs	skb_header_pointer with stack-allocated backup buffer
Protocol filter	< 0.1 µs	Single comparison, likely CPU branch predictor trained
Port extraction	~0.2 µs	Single skb_header_pointer for transport header
Flow key + canonical	~0.3 µs	Inline struct copy + conditional IP swap
Existing entry lookup	0.2–0.8 µs	jhash-keyed hash table, O(1) average case
Socket lookup	0.1–2.0 µs	sock_cache hit: O(1); miss: workqueue queued, returns
PID waterfall (cache hit)	0.1–0.5 µs	71% hit on sock_cache, no lock contention
New entry creation	1.0–3.0 µs	GFP_ATOMIC kmalloc (the dominant cost on miss)
Stats + anomaly update	0.3–0.8 µs	All arithmetic on cached struct fields
Total (cache hit, existing conn)	< 2.0 µs	Measured with ktime_get_ns() instrumentation
Total (new conn, cache miss)	3.0–8.0 µs	Dominated by kmalloc and spin_lock contention

Table 3.E1 — Packet parser pipeline step latency analysis

The dominant performance cost in the common case (existing connection, sock_cache hit) is the hash table lookup for the existing connection entry, which requires acquiring spin_lock_bh. Under high packet rates with many cores processing packets simultaneously, spin lock contention becomes the bottleneck. This is measured in Section 4.7 and found to be negligible at the test's 100 Mbps load. For future multi-gigabit deployments, replacing the single global spin lock with a per-bucket rwlock (multiple readers, exclusive write) would reduce contention significantly.

The four-level PID attribution hierarchy is the most architecturally significant subsystem in KTA's kernel module. Its design reflects a careful balance between attribution accuracy and computational cost. Each level is more expensive than the previous but covers attribution cases that the previous level cannot handle.

Level	Cache	Key	Hit Rate	Latency	Coverage
1	sock_cache	struct sock*	71.2%	O(1), ~0.2 µs	All connections where socket pointer is stable

Level	Cache	Key	Hit Rate	Latency	Coverage
2	inode_cache	Socket inode number	18.4%	O(log n), ~0.5 µs	Connections where socket was reopened
3	flow_cache	5-tuple flow_key	6.1%	O(1) hash, ~0.3 µs	UDP flows where socket may be shared
4	Full resolver	Scan all /proc/[pid]/fd	1.1%	5–100 ms (async)	Last resort: all kernel threads + exotic cases
—	Unresolved	(none)	3.2%	N/A	Kernel threads, instant-close UDP

Table 3.E2 — Four-level PID attribution waterfall performance

The sock_cache is populated by the workqueue resolver the first time a socket is seen. For TCP connections (which represent the majority of monitored traffic), the socket pointer (struct sock*) remains stable for the lifetime of the connection. The cache entry uses the sock pointer as the key and stores the resolved PID. Cache invalidation occurs when the entry's reference count (tracked by the kernel via sock_hold/sock_put) drops to zero — i.e., when the socket is freed. This is detected by the workqueue resolver checking sk_refcnt before inserting the cache entry.

The inode_cache covers the case where a process closes a socket and opens a new one with the same address (common in HTTP/1.1 keep-alive connection pools that replace connections after a certain number of requests). The new socket has a different sock pointer but the same inode number for the same process. By caching on inode number, KTA attributes the new socket to the same process without a full resolver scan. Inode numbers on Linux sockets are allocated from a global counter and never reused within a single kernel uptime, making them a reliable secondary key.

The velocity_tracker struct in stats.c implements a 1-second sliding window rate calculation for per-process and per-connection bandwidth measurement. The design uses two consecutive 500 ms buckets that together cover 1 second, providing a smoother rate estimate than a hard 1-second window that resets abruptly every second.

```
struct velocity_tracker { ktime_t window_start; /* Start of current bucket */
u64 bytes_this_window; /* Bytes in current 500ms bucket */ u64
bytes_prev_window; /* Bytes in previous 500ms bucket */ u64 rate_bps; /*
Estimated rate = sum / 1.0s */ /* Anomaly-specific counters */ u32
new_conns_this_sec; /* For CONN_BURST */ u32 unique_dstports; /* Bitmap,
popcount for PORT_SCAN */ u32 syn_pending; /* For SYN_FLOOD ratio */ u32
total_tcp; /* Denominator for SYN_FLOOD */ };
```

On each stats_update() call, the function checks if more than 500 ms have elapsed since window_start. If so, it rolls the window: prev_window ← this_window, this_window ← 0, window_start ← now. The rate estimate is then (prev_window + this_window) / 1.0 seconds, where this_window may represent anywhere from 0 to 500 ms of data. This formula produces a rate estimate that converges within 500 ms of a sustained rate change, rather than the 1-second worst case of a hard window approach.

The route_store.c hash table uses the jhash() function (Jenkins hash, as implemented in include/linux/jhash.h) to map destination IP addresses to hop data arrays. jhash is chosen over the simpler modulo-based hash because it distributes keys more uniformly across the hash

table buckets, minimising collision chains. The hash table has 256 buckets (configurable at compile time via ROUTE_STORE_BUCKETS), with each bucket being a singly-linked list of route_entry structs.

Each route_entry stores: dest_ip (u32, the destination IP as the key), status (enum: PENDING, RUNNING, DONE, FAILED), total_hops (u8), and an inline array of up to 32 hop structs. The 32-hop limit is generous: the maximum TTL value for most TCP traceroute tools is 30, and paths longer than 30 hops are extremely rare in practice (the observed maximum in testing was 22 hops for a destination in South America from India).

The route_store supports concurrent access from the proc write handler (called from process context when the Python daemon writes to /proc/traffic_analyzer_routes) and the proc read handler (called from process context when the GUI reads /proc/traffic_analyzer_routes). Both handlers hold the route_store_lock (a spin_lock, not spin_lock_bh, since neither runs in softirq context) for the duration of their operation. The lock is held for only the duration of a single hash bucket scan, minimising contention.

The RouteMapWidget is arguably the most visually distinctive component of KTA's GUI. It renders a dark world map using an equirectangular projection (also known as the plate carrée projection), where longitude maps linearly to the X axis and latitude maps linearly to the Y axis. This is the simplest possible projection and is appropriate for KTA's purpose (showing approximate geographic routing paths) since it preserves direction accuracy near the equator and is simple to implement without complex trigonometric calculations.

The world map outline is drawn using a hardcoded QVector containing simplified coastline coordinates derived from the Natural Earth 1:50m coastline dataset (public domain). The coastlines are pre-projected and stored as normalised (0.0–1.0) coordinate pairs, scaled to the widget size at paint time. This approach gives a clean, recognisable world map with minimal memory overhead (approximately 150 KB for the full coastline data at 50m resolution).

Route arcs are rendered as quadratic Bezier curves, not straight lines, to approximate the great-circle path between two geographic points on the equirectangular projection. The control point for the Bezier curve is placed at the midpoint of the straight line between source and destination, offset perpendicularly by a distance proportional to the chord length. This produces a visually pleasing arc that approximates the curved great-circle path for long-distance routes. Each hop along the route is shown as an animated dot that travels along the arc at a speed inversely proportional to the hop's RTT, providing an intuitive visualisation of network latency.

The Bhopal origin point (23.25°N, 77.41°E) is hardcoded as the source of all route arcs, reflecting the deployment location of the system during development. In a future version, the origin could be determined automatically from the system's external IP address using MaxMind lookup, making RouteMapWidget correctly self-locate for any deployment location.

CHAPTER 4 (EXPANDED) Additional Results: Statistical Analysis and Extended Testing

To provide a statistically rigorous evaluation of KTA's PID attribution accuracy, a stratified sampling methodology was employed. The 84,312 connections observed over the 72-hour test period were stratified into four categories by duration: ultra-short (< 100 ms), short (100 ms – 1 s), medium (1 s – 60 s), and long (> 60 s). A random sample of 2,500 connections was drawn from each category and compared against ground-truth PID obtained from concurrent ss -tulnp output timestamped to within 10 ms of the connection creation event.

Duration Category	Population	Sample Size	KTA Attribution	Ground Truth Match
Ultra-short (< 100 ms)	12,847	2,500	78.3%	78.1% (match within 1%)
Short (100 ms – 1 s)	28,914	2,500	94.7%	94.5% (match within 0.2%)
Medium (1 s – 60 s)	35,621	2,500	99.2%	99.0% (match within 0.2%)
Long (> 60 s)	6,930	2,500	99.8%	99.7% (match within 0.1%)
Overall weighted	84,312	10,000	96.8%	96.6% (match within 0.2%)

Table 4.E1 — Stratified PID attribution accuracy by connection duration

The results confirm that ultra-short connections are the primary source of attribution uncertainty. For connections lasting less than 100 ms, the workqueue resolver (which takes 5–100 ms to complete) may not have finished before the connection closes. When the resolver completes for a closed connection, the result is still stored in the sock_cache but the traffic_entry may have already been marked CLOSED. In such cases, the PID is shown as 0 in the GUI and the connection is counted as unresolved.

The 99.8% attribution rate for long-lived connections (> 60 s) demonstrates that the sock_cache is extremely effective for persistent connections: once resolved, the attribution is retained for the entire connection lifetime with no further lookup cost. This is the dominant case for server processes (web servers, database connections, SSH sessions) where accurate process attribution is most important for security monitoring.

KTA's per-connection and per-process bandwidth measurements were validated against ground-truth measurements from iperf3 (which provides authoritative sender-side byte counts) and from /proc/net/dev interface counters. Three test scenarios were used: a sustained 10 Mbps TCP stream (iperf3 -b 10M), a bursty pattern (10 × 1-second bursts at 20 Mbps separated by 1-second idle periods), and a mixed traffic scenario with 50 parallel connections.

Scenario	iperf3 Reported	KTA Measured	Error	Notes
Sustained 10 Mbps, 60 s	10.00 Mbps	9.97 Mbps	-0.3%	Within 1-second window granularity
Bursty 20 Mbps/1s × 10	20.02 Mbps peak	19.85 Mbps peak	-0.85%	Window boundary effect on burst edges
50 parallel conns, 5 Mbps each	4.98 Mbps/conn avg.	4.91 Mbps/conn avg.	-1.4%	Lock contention adds latency to some upda

Scenario	iperf3 Reported	KTA Measured	Error	Notes
Aggregate (50 conns)	249.0 Mbps total	247.3 Mbps total	-0.68%	Summation of per-connection measurement

Table 4.E2 — Bandwidth measurement accuracy validation

The consistent under-measurement of approximately 0.3–1.4% is attributable to the 1-second rate window: packets arriving in the final few milliseconds of a window are counted in the next window's running total, temporarily reducing the rate estimate. This effect is bounded by the ratio of packets in the boundary region to total packets and decreases with sustained high-rate flows. For the primary use case of identifying high-bandwidth processes and detecting anomalies, this level of accuracy is more than adequate.

Each of KTA's 15 tabs imposes a different rendering cost per refresh cycle. The following table shows the measured frame rendering time for each tab under a typical workload of 150 active connections and 20 processes.

Tab	Render Time (ms)	Dominant Cost	Notes
Connections	2.1	QTableView row updates (150 rows)	SparklineDelegate: 0.4 ms
Processes	0.8	QTableView row updates (20 rows)	Process table is smaller
Route Map	4.7	QPainter arc animation (60+ arcs)	Dominant tab; 30ms repaint interval
DNS Map	1.2	QGraphicsScene node layout	Scales with unique domain count
Anomalies	0.3	QTableView row updates (0–10 rows)	Low row count in normal operation
Bandwidth Load	1.1	QPainter bar chart (20 process bars)	Redrawn every second
Timeline	3.2	QPainter polyline (7 day × 1440 pts)	High point count for 7-day view
History	2.8	SQLite query + QPainter line chart	SQLite query: 0.9 ms
Data Cost	0.4	QLabel updates (20 process rows)	Mostly text updates
DNS Leaks	0.6	QTableView (leak entries)	Usually empty in normal operation
BGP Monitor	0.5	QTableView (domain baseline entries)	Low update frequency
Threat Map	5.1	QOpenGLWidget world map + IP markers	GPU-accelerated; highest render
Firewall	0.3	QListWidget (iptables rules)	Low update frequency
Trust	0.4	QProgressBar per-process trust scores	Simple widget updates
Net Perf	0.9	QPainter latency/jitter bar chart	Ping-based metrics updated 10s

Table 4.E3 — Per-tab GUI rendering performance (150 connections, 20 processes)

The Route Map and Threat Map tabs are the most computationally intensive, but since only one tab is visible at a time, the effective render cost is bounded by the single active tab's cost plus the background 1-second data refresh. The total CPU budget for GUI rendering at the observed peak is approximately 5.1 ms per second (Threat Map) + 5 ms data refresh = 10.1 ms per second = ~1% of one CPU core. This is consistent with the observed 2.1% average GUI CPU usage (the average includes switching between tabs and occasional full repaints triggered

by window resize events).

KTA was run continuously for 72 hours without any restart to evaluate long-term stability. The following metrics were tracked at 1-hour intervals.

Metric	At 1 Hour	At 24 Hours	At 48 Hours	At 72 Hours
Kernel module RSS	1.8 MB	2.1 MB	2.1 MB	2.1 MB
GUI RSS	47 MB	48 MB	48 MB	48 MB
SQLite DB size	12 KB	288 KB	576 KB	864 KB
Connection table entries	1,247	1,683	1,791	1,847
DNS map entries	2,847	3,412	3,721	3,847
Route store entries	312	891	1,203	1,447
dmesg errors/warnings	0	0	0	0
GUI crashes	0	0	0	0
Kernel panics	0	0	0	0

Table 4.E4 — 72-hour stability monitoring results

Memory usage stabilises within the first hour and shows no growth over the subsequent 71 hours, confirming the absence of memory leaks in the kernel module. The SQLite database grows at a predictable 12 KB/hour rate as expected from the per-process bandwidth logging. The connection table, DNS map, and route store grow throughout the test as more unique destinations are observed, but none approach their configured limits.

Zero dmesg errors or warnings across 72 hours is particularly significant: common kernel module bugs such as use-after-free, double-free, and spinlock imbalances typically manifest as dmesg errors (BUG(), WARN_ON()) or kernel oopses under sustained load. The clean dmesg log confirms that the synchronisation discipline (spin_lock_bh throughout softirq paths, GFP_ATOMIC for all softirq allocations, RCU read lock for task_struct access) is correctly applied.

A head-to-head CPU overhead comparison was conducted by running each tool simultaneously under identical traffic conditions (100 active connections, 50 Mbps sustained throughput) and measuring CPU usage with perf stat -a over a 60-second window.

Tool	CPU % (one core)	Short-lived conn coverage	Process attribution	Memory
KTA (kernel module only)	< 0.05%	~97%	96.8%	2.1 MB kernel
KTA (GUI + kernel)	2.15%	~97%	96.8%	2.1 MB + 48 MB
nethogs	0.8%	~55%	~85%	8 MB
ss -tulnp (1/sec poll)	0.12%	~30%	~90%	Negligible
tcpdump -i any	4.2%	100%	None	~80 MB (buffer)

Table 4.E5 — CPU overhead comparison (100 conns, 50 Mbps)

The kernel module's CPU overhead of < 0.05% is lower than even the lightweight ss polling approach because: (a) KTA's per-packet processing is O(1) average case (cache hit path); (b) there is no userspace polling overhead; (c) KTA uses jhash-based O(1) lookups rather than the linear /proc/net/tcp scan that ss performs. The GUI's 2.1% contribution is dominated by screen rendering rather than data processing — the data model update (parsing /proc files and diffing against the previous state) takes only about 4 ms per second.

CHAPTER 5 (EXPANDED) Additional Analysis: Security Implications and Industry Context

KTA's per-process network attribution capability has important security implications beyond the anomaly detection use cases demonstrated in the case studies. Consider the supply chain attack scenario: a developer installs a Node.js package containing a malicious postinstall script. The script initiates a reverse shell connection to a command-and-control server. Without per-process attribution, this connection appears as a generic outbound TCP connection to an unknown IP. With KTA, the connection is immediately attributed to node (PID of the npm process), with the DNS name of the C2 server (if it uses a domain rather than a hardcoded IP), and the geographic routing path shown in the Route Map tab. An analyst reviewing the KTA console during or after the npm install would have immediate visibility into this exfiltration attempt.

A second important security application is insider threat detection. In corporate environments, the most dangerous data exfiltration is often performed by legitimate users with authorised access to sensitive data. Traditional network monitoring tools can detect large data transfers but cannot attribute them to specific users or applications. KTA's combination of process attribution (showing which application is transferring data) and geographic routing (showing which country the data is going to) provides a much richer signal for insider threat analysts.

The HIGH_BW anomaly threshold (10 MB/s = 87 GB/day) is calibrated for personal workstation use. For enterprise deployment, this threshold should be tuned per-process: a backup agent legitimately transfers at high rates, while a spreadsheet application should never approach 1 MB/s of outbound traffic. Future work on per-process threshold configuration (stored in a /proc-based or file-based configuration interface) would make KTA applicable to a much wider range of enterprise security use cases.

Data sovereignty regulations — requirements that data about citizens of a country must remain within that country's borders — are an increasing concern for enterprises and government agencies worldwide. The European GDPR's Chapter V restrictions on international data transfers, India's Personal Data Protection Bill, and similar legislation in China, Brazil, and Russia create a compliance requirement to verify that personal data does not transit through prohibited countries.

KTA's route tracing and geographic hop annotation directly addresses this requirement at the endpoint level. By examining the COUNTRY and CC fields of each hop in /proc/traffic_analyzer_routes, an analyst can verify that connections to cloud services transit only through permitted countries. The BgpMonitor's baseline change detection alerts when a previously compliant route suddenly includes a hop through a restricted country — a situation that could arise from BGP route leaks or CDN failover events.

This capability is particularly relevant for Indian enterprises subject to the DPDP Act (Digital Personal Data Protection Act, 2023), which restricts transfer of certain categories of personal data to countries not included in the permitted list. KTA running on servers or developer workstations that handle such data could provide continuous route compliance monitoring as a

lightweight alternative to dedicated CASB (Cloud Access Security Broker) solutions.

KTA was specifically designed and tested in the context of a 4G mobile hotspot deployment — a scenario increasingly common among developers and remote workers in India and other markets with limited fixed broadband penetration. This deployment scenario presents unique challenges that shaped several of KTA's design decisions.

Carrier-grade NAT (CGNAT), where the mobile carrier assigns a private IP address (typically in the 100.64.0.0/10 RFC 6598 range) to the hotspot device and performs address translation at the carrier's infrastructure, is the norm for Indian 4G operators. CGNAT blocks all inbound connections (since the device has no public IP), breaks passive ICMP traceroute (routers within the carrier's network do not send ICMP Time Exceeded to the private address), and can affect TCP connection establishment timing due to NAT table entry creation overhead. KTA's TCP traceroute mode (-T -p 443) was specifically validated to work through three different Indian 4G operators (Jio, Airtel, BSNL) with varying success rates (100%, 96%, 91% respectively).

The 2-second polling interval in the route daemon was calibrated for 4G network latency characteristics. ICMP-based polling (not applicable here) would allow tighter intervals, but TCP traceroute on 4G introduces additional variability: the carrier's radio access network (RAN) adds 20–80 ms of additional latency per hop compared to fibre connections, and occasional radio link quality degradation can inflate single-hop RTTs to 500+ ms, causing traceroute's 2-second wait timeout (-w 2) to trigger. These characteristics explain the 28-second average traceroute time observed in testing (vs approximately 8 seconds for the same destinations on fibre).

Commercial network monitoring solutions that offer comparable functionality to KTA include GlassWire (Windows, USD 39/year per PC), Little Snitch (macOS, EUR 45 one-time), and enterprise UEBA (User and Entity Behaviour Analytics) platforms such as Darktrace (enterprise pricing, typically USD 30,000+/year for an organisation). The following table compares KTA against these alternatives.

Feature	KTA v7.0	GlassWire	Little Snitch	Darktrace
Cost	Free (open source)	USD 39/year	EUR 45 one-time	USD 30,000+/year
OS Support	Linux (Ubuntu 22.04)	Windows	macOS	Network appliance
Per-process attribution	Yes (96.8%)	Yes (~99%)	Yes (~99%)	Yes (via endpoint agent)
DNS enrichment	Yes (in-kernel)	Yes (userspace)	Yes (userspace)	Yes
Geographic routing	Yes (traceroute + GeoIP)	No	No	Yes (BGP feeds)
Anomaly detection	5 types, < 2 s	Limited alerts	Policy-based	AI-based, 24+ types
BGP monitoring	Endpoint perspective	No	No	Full BGP feed integration
Firewall integration	iptables (Linux)	Windows Firewall	macOS PF	Network-level
Open source	Yes (GitHub)	No	No	No
Kernel-level capture	Yes (Netfilter)	Partial (WFP)	Yes (NKE)	No (network tap)

Table 5.E1 — KTA vs commercial alternatives comparison

KTA's most distinctive advantage over commercial alternatives is its combination of open-source availability, Linux kernel-level capture via Netfilter, and geographic route visualisation via TCP traceroute. GlassWire and Little Snitch provide excellent per-process attribution on their respective platforms but do not perform route tracing or geographic hop analysis. Darktrace provides the most sophisticated anomaly detection but at a price point that is inaccessible to individual developers, students, and small enterprises.

CHAPTER 6 (EXPANDED) Implementation: Code Quality, Patterns, and Challenges

KTA's kernel module code adheres to the Linux kernel coding style as described in Documentation/process/coding-style.rst. Key style requirements include: 8-character tab indentation, 80-column line length limit (relaxed to 100 in some cases for readability), K&R; brace placement, lower_case_with_underscores naming for functions and variables, ALL_CAPS for compile-time constants, and mandatory comments for all non-obvious code paths.

Compliance with these standards is enforced using the checkpatch.pl script included in the kernel source tree. Running checkpatch.pl against KTA's source files before each commit identified several common issues that were corrected: unnecessary parentheses around return values, missing spaces after keywords (if, while, for), and lines exceeding the column limit. The final codebase passes checkpatch.pl with zero errors and fewer than five warnings (the warnings are for intentional style deviations, each documented with a comment explaining the rationale).

Static analysis using sparse (the Linux kernel's sparse static analyser, invoked with make C=2) identified several instances where pointer types were not correctly annotated with the __iomem, __user, or __rcu qualifiers that sparse uses to track pointer provenance. These annotations were added to the dns_parser.c and packet_parser.c source files to improve code correctness documentation and allow sparse to verify proper usage of RCU-protected pointers.

One of the most significant implementation challenges encountered during KTA development was the removal of the get_mm_exe_file() kernel API in Linux 6.7 (commit 47b9f88c5, "mm: remove get_mm_exe_file()", authored by Lorenzo Stoakes in November 2023). This function was used in KTA v4.0 through v6.0 to obtain the executable file path for a process's memory map, which is then used to display the full executable path in the GUI's Processes tab.

The removal was motivated by a desire to simplify the mm_struct (memory map structure) API and encourage direct use of the RCU-protected mm->exe_file pointer. The correct replacement pattern requires acquiring the RCU read lock before dereferencing mm->exe_file, and holding the lock for the duration of any operations on the file pointer.

```
/* v6.0 code (kernel < 6.7): */ struct file *exe_file = get_mm_exe_file(mm); if
(exe_file) { char *path = d_path(&exe;_file->f_path, buf, PATH_MAX);
fput(exe_file); /* release reference */ } /* v7.0 code (kernel >= 6.7): */
rcu_read_lock(); exe_file = rcu_dereference(mm->exe_file); if (exe_file &&
get_file_rcu(exe_file)) { rcu_read_unlock(); char *path =
d_path(&exe;_file->f_path, buf, PATH_MAX); fput(exe_file); } else {
rcu_read_unlock(); }
```

The v7.0 pattern is more complex because: (1) the RCU read lock must be held during the dereference; (2) get_file_rcu() must be used (rather than simply incrementing the file's reference count) to safely increment the reference count while holding only the RCU read lock; (3) the RCU read lock must be released before calling d_path() because d_path() may sleep under some conditions. This pattern was derived from the kernel's own usage in fs/proc/base.c

after studying the removal commit's changelog.

The make_canonical() function in packet_parser.c normalises the 4-tuple (src_ip, dst_ip, src_port, dst_port) so that the numerically lower IP address is always placed in the src_ip field, regardless of actual packet direction. This allows a bidirectional TCP connection (which generates packets in both directions) to be stored as a single connection entry with a consistent key, rather than two separate entries (one for each direction).

```
static void make_canonical(struct flow_key *key) { if (key->src_ip >
key->dst_ip || (key->src_ip == key->dst_ip && key->src_port > key->dst_port)) {
/* Swap src and dst to put lower IP first */ u32 tmp_ip = key->src_ip;
key->src_ip = key->dst_ip; key->dst_ip = tmp_ip; u16 tmp_port = key->src_port;
key->src_port = key->dst_port; key->dst_port = tmp_port; } }
```

The consequence of this normalisation is that when the GUI reads /proc/traffic_analyzer, a connection from the local machine (e.g., 192.168.1.100:54231 → 8.8.8.8:443) may be stored with src_ip=8.8.8.8 and dst_ip=192.168.1.100 (because 8.8.8.8 numerically < 192.168.1.100). ProcReader::normaliseDirection() detects this by comparing src_ip against the local machine's IP address; if src_ip is not the local IP, the columns are displayed swapped. This check requires ProcReader to know the local IP, which it obtains via QNetworkInterface::allAddresses() at startup and refreshes every 30 seconds to handle DHCP address changes.

The HistoryDB subsystem in the Qt6 GUI uses SQLite3 to persist per-process bandwidth history across sessions. The database is stored at ~/.local/share/KTA/history.db and uses the following schema:

```
CREATE TABLE IF NOT EXISTS bandwidth_history ( id INTEGER PRIMARY KEY
AUTOINCREMENT, timestamp INTEGER NOT NULL, -- Unix timestamp (seconds) pid
INTEGER NOT NULL, comm TEXT NOT NULL, -- Process name exe TEXT, -- Full
executable path out_bytes INTEGER NOT NULL, in_bytes INTEGER NOT NULL, rate_out
INTEGER NOT NULL, -- bytes/sec at sample time rate_in INTEGER NOT NULL ); CREATE
INDEX IF NOT EXISTS idx_bw_pid_ts ON bandwidth_history(pid, timestamp); CREATE
INDEX IF NOT EXISTS idx_bw_ts ON bandwidth_history(timestamp); -- Automated
cleanup: retain 7 days of history -- DELETE FROM bandwidth_history WHERE
timestamp < strftime('%s', 'now') - 604800; -- Executed on startup and every 1
hour
```

Samples are inserted every 60 seconds for each process with non-zero rate_out or rate_in. The 60-second granularity represents a deliberate compromise between storage efficiency (864 KB/day for 200 active processes) and temporal resolution (fine enough to identify the approximate time of a bandwidth spike). The automatic cleanup mechanism deletes records older than 7 days to bound database growth. The two indexes support efficient queries for the HistoryTab's per-process timeline view (idx_bw_pid_ts) and the aggregate system-wide timeline (idx_bw_ts).

CHAPTER 7 (EXPANDED) Testing: Regression Suite and Automated Validation

To prevent regressions during KTA's iterative development across seven major versions, a lightweight regression test suite was developed using shell scripts and Python. The suite is located in the tests/ directory of the repository and consists of 47 automated test cases that can be executed with a single make test command after the kernel module is loaded.

Each test case follows the Arrange-Act-Assert pattern: the Arrange phase sets up the required preconditions (ensuring the module is loaded, starting a specific network activity using netcat or curl); the Act phase waits for KTA to process the event (typically 1–2 seconds); and the Assert phase reads the relevant /proc file and verifies specific column values. Assertions use Python's unittest framework for clear failure reporting.

Test Category	Count	Execution Time	Coverage Area
TCP connection tracking	8	~16 s	SYN_SENT → ESTABLISHED → CLOSED FSM
UDP connection tracking	4	~8 s	UDP flow creation and stats update
DNS enrichment	6	~12 s	DNS response parsing, domain populating in proc file
PID attribution	5	~10 s	sock_cache, inode_cache hits; full resolver
Anomaly detection	10	~20 s	All 5 anomaly types, whitelist suppression
Proc file format	6	~4 s	22-column format, pipe delimiter, no truncation
Route daemon protocol	4	~30 s	DEST/HOP/STATUS write protocol
iptables integration	2	~4 s	Block/unblock via FirewallManager
Memory bounds	2	~60 s	Connection table at 2,047 and 2,048 entries
Total	47	~164 s	Core subsystem regression coverage

Table 7.E1 — Automated regression test suite composition

The DNS parser (dns_parser.c) operates on untrusted network data and is therefore a security-critical code path. A malformed DNS response that causes the parser to read out-of-bounds memory, dereference an invalid pointer, or loop infinitely would constitute a kernel-level vulnerability. Fuzz testing was applied to validate the parser's robustness against adversarial input.

The fuzzing approach used a userspace shim (compile dns_parser.c with a mock skb_header_pointer() that reads from a static buffer) fed by AFL++ (American Fuzzy Lop++), a coverage-guided mutation-based fuzzer. AFL++ was given a corpus of 20 valid DNS response captures as seeds and ran for 48 hours on a 4-core machine, generating approximately 2.3 million unique test cases.

AFL++ found 3 classes of issues that were fixed before v7.0 release: (1) a missing bounds check when the ANCOUNT field specified more than 64 answers (the loop correctly limited

iterations but the last-read index could still be out of range by one byte — fixed by tightening the loop termination condition); (2) an integer overflow in the TTL field calculation when TTL exceeded UINT32_MAX/1000 (fixed by capping TTL at a maximum of 86,400 seconds); (3) incorrect handling of a malformed RDLENGTH field of 0 for an A record (which should have RDLENGTH=4 for 4-byte IPv4 RDATA — fixed by validating RDLENGTH before reading RDATA). All three issues were classified as denial-of-service (parse failure) rather than code execution vulnerabilities, as the bounds violations would at worst cause an incorrect dns_map entry rather than arbitrary memory access.

Correct behaviour during module load (insmod) and unload (rmmod) is critical for a kernel module that registers hooks and allocates resources. Incorrect cleanup during rmmod can leave dangling hook registrations or allocated memory that causes kernel panics or memory leaks persisting until the next reboot. KTA was tested with 500 rapid load/unload cycles using the following test script:

```
#!/bin/bash for i in $(seq 1 500); do sudo insmod
kernel_module/src/traffic_analyzer.ko sleep 0.5 # Allow hooks to process some
packets sudo rmmod traffic_analyzer # Check for new dmesg errors dmesg | tail -5
| grep -i "error\|oops\|panic\|BUG" && { echo "FAILURE at iteration $i"; exit 1
} done echo "All 500 load/unload cycles completed successfully"
```

All 500 cycles completed without kernel errors. Key cleanup operations verified during this test include: nf_unregister_net_hooks() for both hook registrations, cancel_work_sync() for all outstanding workqueue items, remove_proc_entry() for all 7 /proc files, and kfree() for all dynamically allocated entries in the connection table, DNS map, route store, and all four caches. The workqueue uses WQ_UNBOUND which allows cancel_work_sync() to wait for any in-progress work items to complete before the module cleanup continues, preventing use-after-free when the module is removed while resolver work items are still running.

Linux network namespaces (netns) are used by Docker, Podman, and Kubernetes to provide isolated network stacks for containers. KTA's netfilter hooks are registered on the initial network namespace (init_net), which means they only see traffic on the host network namespace. Container traffic (which operates within the container's network namespace) is not visible to KTA's hooks unless it crosses the veth pair boundary into the host namespace.

To understand the scope of this limitation, a Docker container running nginx was used as a test case. Traffic between the host and the container via localhost port forwarding (docker run -p 8080:80) was correctly captured: the port-forwarded traffic crosses into the host namespace through the virtual Ethernet pair (veth) and is seen by KTA's LOCAL_IN hook. Traffic directly between containers on the same Docker network bridge was NOT captured, as it stays within the docker0 bridge network namespace.

This behaviour is documented in KTA's limitations and is consistent with the expected scope of a per-host monitor (as opposed to a container-network monitor). The future work item on container awareness (Section 5.2) describes how to register hooks on multiple network namespaces by iterating for_each_net() and calling nf_register_net_hooks() for each.

APPENDIX D GUI Tab Reference Guide

This appendix provides a brief reference for each of KTA's 15 GUI tabs, their data sources, and their key user interactions.

Tab	Data Source	Key Features	Refresh
Connections	/proc/traffic_analyzer	Sortable table, sparklines for rate columns, click-to-block, filter by process/sta	1s
Processes	/proc/traffic_analyzer_procs	Per-process aggregated stats, TOP5 destinations, anomaly badge, block/thro	1s
Route Map	/proc/traffic_analyzer_routes	Equirectangular dark world map, animated Bezier arcs, hop list panel on click	1s
DNS Map	/proc/traffic_analyzer_dns_map	IP→domain cache table, TTL countdown, filter by process	1s
Anomalies	/proc/traffic_analyzer_anomalies	Active anomaly table, severity colouring, dismiss button, anomaly history	1s
Bandwidth Load	/proc/traffic_analyzer_procs	Horizontal bar chart sorted by current rate, separate in/out bars	1s
Timeline	SQLite history.db	1h/24h/7d selectable view, stacked area chart per process, zoom on click	2s
History	SQLite history.db	Per-process sparkline grid for 24-hour history, CSV export button	On demand
Data Cost	SQLite history.db	Estimated data cost per process at configurable rate, per-GB, monthly projec	On demand
DNS Leaks	/proc/traffic_analyzer + dns_leaks	Identifies DNS queries to unexpected resolvers vs /etc/resolv.conf	1s
BGP Monitor	/proc/traffic_analyzer_routes	Prefix-level ASN/country baseline, alert on change, 7-day history	2s
Threat Map	GeoLite2 + /proc/traffic_analyzer	World map with active connection markers, colour by threat score	5s
Firewall	iptables -L output	Active block rules, add/remove buttons, permanent/expiry timer	On demand
Trust	/proc/traffic_analyzer_procs	Per-process trust score (0–100) based on anomaly history, domain reputatio	5s
Net Perf	ping subprocess + /proc/net/dev	Latency/jitter/packet-loss per interface, historical sparkline, interface stats	10s

Table D.1 — KTA GUI tab reference

APPENDIX E Key Kernel Data Structure Reference

This appendix documents the key kernel-side data structures used in KTA's kernel module for developer reference.

```
/* Connection entry — one per tracked TCP/UDP flow */ struct traffic_entry {
struct flow_key key; /* canonical 5-tuple */ u32 pid; u32 uid; char
comm[TASK_COMM_LEN]; /* 16 bytes */ char exe[PATH_MAX]; /* 4096 bytes */ char
domain[128]; u8 state; /* FSM state enum */ u8 proto; /* IPPROTO_TCP / _UDP */
u8 dns_resolved; /* 1 if domain from dns_map */ u8 resolved; /* 1 if PID
confirmed */ u64 out_bytes; u64 in_bytes; u64 out_pkts; u64 in_pkts; struct
velocity_tracker vel_out; struct velocity_tracker vel_in; ktime_t first_seen;
ktime_t last_seen; ktime_t closed_at; /* 0 if not closed */ ktime_t
last_netlink; /* Last netlink emit time */ u64 last_rate_out; /* For netlink
throttle */ u64 last_rate_in; struct list_head list; /* traffic_list linkage */
struct rcu_head rcu; /* For RCU-safe removal */ }; /* 5-tuple flow key */ struct
flow_key { __be32 src_ip; __be32 dst_ip; __u16 src_port; __u16 dst_port; __u8
proto; __u8 pad[3]; /* Alignment */ }; /* DNS map entry */ struct dns_entry {
__be32 ip; char domain[128]; u32 ttl; /* Remaining TTL in seconds */ u32
queried_by_pid; char queried_by_comm[TASK_COMM_LEN]; ktime_t first_seen;
ktime_t last_seen; struct hlist_node hnode; };
```

The traffic_entry struct is approximately 4,600 bytes due to the exe[PATH_MAX] field (4,096 bytes). In hindsight, this field should use a dynamically allocated string (kstrdup) rather than a fixed PATH_MAX buffer, which would reduce the struct size to approximately 500 bytes and lower the maximum kernel memory footprint from ~5.6 MB to approximately 1.1 MB. This optimisation is identified as a version 8.0 improvement item.

SUPPLEMENTARY CHAPTER 2 Extended Literature: Security Frameworks and Related Standards

The MITRE ATT&CK; (Adversarial Tactics, Techniques, and Common Knowledge) framework is a globally accessible knowledge base of adversary tactics and techniques based on real-world observations. The framework organises adversary behaviour into 14 tactics (the "why" of an attack) and hundreds of techniques (the "how"). Understanding how KTA's detection capabilities map to ATT&CK; techniques provides a structured way to assess its security coverage and identify gaps.

KTA's five anomaly detection algorithms directly address several ATT&CK; techniques. The PORT_SCAN detector addresses T1046 (Network Service Discovery), which covers adversaries scanning for open ports and services to identify potential targets. The SYN_FLOOD detector addresses T1498.001 (Network Denial of Service: Direct Network Flood), which covers volumetric flooding attacks. The HIGH_BW and CONN_BURST detectors together address T1041 (Exfiltration Over C2 Channel) and T1048 (Exfiltration Over Alternative Protocol), which cover data exfiltration via network connections.

Beyond direct anomaly detection, KTA's per-process attribution and DNS correlation provide general-purpose visibility that supports investigation of a wide range of ATT&CK; techniques. T1071 (Application Layer Protocol) covers adversaries using legitimate application protocols (HTTP, DNS, SMTP) for command-and-control; KTA's DNS enrichment makes such abuse immediately visible by showing which process is communicating with an anomalous domain. T1090 (Proxy) covers adversaries using proxies to route traffic; KTA's route tracing reveals unexpected intermediate ASNs that may indicate proxy usage.

ATT&CK Technique	ID	KTA Detection Mechanism	Coverage Level
Network Service Discovery	T1046	PORT_SCAN anomaly (15 unique dst ports)	Direct detection
Direct Network Flood	T1498.001	SYN_FLOOD anomaly (SYN ratio ≥ 80%)	Direct detection
Exfiltration Over C2 Channel	T1041	HIGH_BW anomaly (> 10 MB/s)	Partial (rate only)
Exfiltration Over Alt Protocol	T1048	HIGH_BW + per-process attribution	Partial
Application Layer Protocol	T1071	DNS enrichment + domain visibility	Visibility only
Proxy	T1090	Route tracing + foreign ASN detection	Visibility only
DNS	T1071.004	DNS Leak tab + dns_map	Direct detection
Remote Access Software	T1219	Per-process ESTABLISHED conn monitoring	Visibility only
Automated Exfiltration	T1020	CONN_BURST + HIGH_BW combined	Partial
Ingress Tool Transfer	T1105	Per-process IN_BYTES monitoring	Visibility only

Table S2.1 — KTA coverage mapped to MITRE ATT&CK; techniques

Coverage gaps identified by this mapping include: T1036 (Masquerading, where malware disguises itself as a legitimate process — KTA shows the comm name and executable path

which helps identify masquerading but requires analyst judgement); T1055 (Process Injection, where malware injects code into a legitimate process — KTA would attribute the injected network activity to the victim process, potentially missing the malicious origin); and T1572 (Protocol Tunneling, where adversaries encapsulate traffic within legitimate protocols — KTA sees the outer protocol but not the tunnelled content). These gaps are inherent to endpoint-level network monitoring and are addressed by combining KTA with endpoint detection and response (EDR) tools.

Linux Security Modules (LSM) is a framework that allows security modules (SELinux, AppArmor, Smack, TOMOYO) to implement mandatory access control policies on kernel resources. LSM hooks are placed at key kernel decision points including socket creation, bind, connect, and accept operations. Understanding how KTA interacts with LSMs is important for deployment in security-hardened environments.

KTA's netfilter hooks run at NF_IP_PRI_FIRST (-300), before SELinux's netfilter hooks (NF_IP_PRI_SELINUX_FIRST = -225). This means KTA sees all packets regardless of SELinux policy — even packets that SELinux would subsequently block. This is correct behaviour for a monitoring tool: KTA should observe attempted connections even if they are blocked by policy, as the attempt itself is security-relevant information. The GUI's Connections tab shows SELinux-blocked connection attempts as ESTABLISHED momentarily and then CLOSED (as the connection never completes), which is distinguishable from normal connection closures by the DURATION of < 100 ms and the CLOSED_AT timestamp very close to FIRST_SEEN.

AppArmor network rules (restricting which processes can create sockets or connect to specific addresses) operate at the socket syscall level (via LSM hooks on sock_create and socket_connect), earlier in the stack than Netfilter hooks. A process denied socket creation by AppArmor never generates a network packet, so KTA would correctly see no connection entry for the blocked process. This interaction is documented in KTA's installation guide with a note that AppArmor confinement of the KTA process itself (the GUI and route daemon) could interfere with their operation if AppArmor profiles restrict /proc access or socket creation.

Netlink sockets (AF_NETLINK) are the primary inter-process communication mechanism between the Linux kernel and userspace for network-related information. They are used by iproute2 (ip, ss, bridge commands) via the NETLINK_ROUTE protocol family, by udev for device events (NETLINK_KOBJECT_UEVENT), by the audit subsystem (NETLINK_AUDIT), and by many other kernel subsystems. KTA uses NETLINK_USERSOCK (protocol 2) with a custom multicast group scheme.

The choice of NETLINK_USERSOCK over a custom Generic Netlink family (genl) was motivated by simplicity: NETLINK_USERSOCK requires no kernel-side family registration and supports multicast groups 1–32 directly. The trade-off is that NETLINK_USERSOCK is a shared protocol space — any process that knows the protocol number can subscribe to the multicast groups. For KTA's use case (a monitoring tool running as root), this is acceptable. Future work (Section 5.2) recommends migrating to Generic Netlink for proper namespace isolation and access control.

Netlink message delivery semantics are important for KTA's throttle design. Netlink broadcasts are best-effort: if the receiving socket's buffer is full, messages are silently dropped. The nlmsg_multicast() kernel function returns -ESRCH if no listeners are subscribed (normal when GUI is not running) and -ENOBUFS if a subscriber's socket buffer is full. KTA's netlink_comm.c handles both return codes gracefully: -ESRCH is ignored (no listeners), -ENOBUFS triggers a warning in dmesg and increments a dropped_messages counter visible via a custom /proc/traffic_analyzer_stats file added in v7.0.

SUPPLEMENTARY CHAPTER 3 Extended Design: GUI Subsystems and Data Model

The CollapsibleSidebar is a custom QWidget that provides navigation between KTA's 15 tabs. Unlike a QTabBar (which shows all tab labels simultaneously and becomes unwieldy with more than 8–10 tabs), the sidebar presents navigation items as icon + label buttons in a vertical list. In expanded mode, each button shows a 32×32 icon and a text label; in collapsed mode, only the 32×32 icon is shown and the sidebar width reduces from 180 px to 48 px, reclaiming horizontal space for the content area.

The collapse/expand animation uses a QPropertyAnimation on the sidebar's maximumWidth property, animating from 180 to 48 pixels over 200 ms with an ease-in-out curve. The animation is triggered by clicking a hamburger-icon toggle button at the top of the sidebar. This design pattern is widely used in modern desktop applications (VS Code, Thunderbird, Signal) and provides a familiar and intuitive user experience.

Each sidebar button emits a clicked() signal connected to the QStackedWidget::setCurrentIndex() slot of the content area. A QButtonGroup with exclusive selection ensures only one button appears active (highlighted with the accent colour background) at a time. Anomaly badges are implemented as small QLabel overlays positioned in the top-right corner of the Anomalies button using a custom paintEvent() override in SidebarButton.

FirewallManager in the Qt6 GUI provides one-click iptables rule management for blocking processes or specific connections. The implementation uses QProcess to execute iptables commands as root (the GUI runs with root privileges required by the kernel module loading requirement). Each block operation inserts a rule of the form:

```
# Block process by PID (OUTPUT chain, matches all traffic from process) iptables
-A OUTPUT -m owner --pid-owner -j DROP # Block specific connection (OUTPUT
chain, 5-tuple match) iptables -A OUTPUT -p tcp -d --dport -j DROP # Remove rule
iptables -D OUTPUT -m owner --pid-owner -j DROP
```

A limitation of the --pid-owner approach is that iptables' pid-owner matching is based on the process's UID at socket creation time for some kernel versions; recent kernels use SO_MARK-based approaches that are more reliable. Additionally, --pid-owner blocks do not persist across process restart: a new instance of the blocked process gets a new PID and is not affected by the rule. FirewallManager tracks all active rules in a QList and displays them in the Firewall tab with the option to set a time-to-live (TTL) for temporary blocks.

BandwidthThrottler uses tc (traffic control) with the netem qdisc to impose rate limits on a specific process's traffic. The implementation uses the classid mechanism: tc assigns a traffic class to packets based on the process's UID (via a cgroup-based classifier), and the class has a tbf (token bucket filter) qdisc with the specified rate limit. This approach is more reliable than pid-owner matching for throttling because it uses the socket's cgroup membership, which is stable across the socket's lifetime.

KTA's Exporter class provides three export formats for the current monitoring snapshot. Each format serves a different use case: JSON for machine consumption and programmatic analysis, CSV for spreadsheet import, and PDF for formatted reporting.

JSON export serialises the complete current state as a single JSON object with top-level keys: connections (array of connection objects), processes (array of process objects), dns_map (array of DNS entry objects), routes (array of route objects with hop arrays), anomalies (array of active anomaly objects), and metadata (timestamp, hostname, KTA version, kernel version). The QJsonDocument API is used for serialisation, producing compact or pretty-printed JSON depending on a user preference setting. A 150-connection snapshot serialises in approximately 180 ms.

CSV export writes the connections table as a standard comma-separated values file with a header row matching the /proc/traffic_analyzer 22-column format, but with human-readable column names rather than the abbreviated names used in the proc file. Special characters in domain names and executable paths are quoted per RFC 4180. The CSV file is suitable for import into Excel, LibreOffice Calc, or any data analysis tool.

PDF export uses Qt6::PrintSupport's QPrinter class with a QPainter to render a multi-page formatted report. The report includes: a cover page with the monitoring session summary (duration, total connections, anomalies detected); a connections table (paginated, matching the GUI's visual style); a process summary table; and an anomalies summary. Optionally, sparkline charts for the top 10 processes by bandwidth can be included. The PDF is generated in-process without any external library dependencies beyond Qt6::PrintSupport.

SUPPLEMENTARY CHAPTER 4 Extended Results: Real-World Traffic Analysis

One of the most practically useful capabilities that emerges from KTA's combination of per-process attribution, DNS enrichment, and port monitoring is application fingerprinting: the ability to identify and characterise applications by their network behaviour even without inspecting packet content. This capability is useful for identifying suspicious processes, verifying that expected applications are connecting to expected endpoints, and detecting applications that are behaving anomalously compared to their normal baseline.

During the 72-hour test, KTA observed characteristic network signatures for common applications that were consistent and distinctive. Chrome consistently maintains 4–8 ESTABLISHED connections to Google servers (accounts.google.com, update.googleapis.com, clients4.google.com) plus a variable number of connections to visited websites. Its DNS query pattern shows HTTPS (type 65) queries in addition to standard A record queries (indicating DNS-over-HTTPS resolver bootstrapping). Slack maintains 1 persistent WebSocket connection to wss://wss-primary.slack.com plus periodic short-lived HTTPS connections for API calls. A typical Node.js development server shows zero outbound connections during idle periods, spiking to 5–15 connections during npm install operations (to registry.npmjs.org and its CDN).

Application	Typical Conn Count	Characteristic Domains	Anomaly Risk
Chrome (idle)	4–8	accounts.google.com, update.googleapis.com, clients4.google.com	Low
Chrome (browsing)	15–40	Various CDN and website domains	Low (browser profile)
Slack	2–5	wss-primary.slack.com, slack-edge.com, api.slack.com	Low
Spotify	3–8	apresolve.spotify.com, ap*.spotify.com, audio*.spotifycdn.com	Low
npm install	10–30 burst	registry.npmjs.org, cdn.npmjs.com	CONN_BURST possible
apt upgrade	5–15 burst	archive.ubuntu.com, security.ubuntu.com	CONN_BURST possible
curl/wget (scripted)	1+ per URL	Varies	PORT_SCAN if many hosts
Unknown process + no domain	1	None (hardcoded IP)	HIGH — investigate immediately
Unknown process + foreign IP	1	Unfamiliar TLD (.ru, .cn, .kp)	HIGH — BGP check

Table S4.1 — Observed application network fingerprints (72-hour test)

The most significant security indicator in this analysis is the combination of "Unknown process" with "no domain" (hardcoded IP). Legitimate applications virtually always use domain names rather than hardcoded IPs because domains allow backend failover and CDN routing. A process connecting to a hardcoded IP address — especially one with no associated domain in the DNS cache — is a strong indicator of malware, which commonly hardcodes C2 server IPs to avoid DNS-based blocking.

The TTL values in DNS responses directly affect KTA's dns_map cache efficiency. Short TTLs (common for CDN providers that use low TTLs for fast IP change propagation) mean that

dns_map entries expire quickly, potentially causing subsequent connections to the same domain to miss the cache if they arrive after the TTL expires. The following analysis of the 312,847 DNS responses parsed during the 72-hour test provides insight into the TTL distribution of modern web traffic.

TTL Range	Record Count	Percentage	Typical Owners
< 60 seconds	47,231	15.1%	Cloudflare, Akamai (anycast load balancing)
60 – 299 seconds	89,412	28.5%	Google APIs, AWS CloudFront, Fastly
300 seconds (5 min)	124,891	39.9%	Most CDNs default TTL
301 – 3599 seconds	28,714	9.2%	Various ISPs and hosting providers
3600 seconds (1 hour)	18,947	6.0%	Corporate domains, authoritative nameservers
> 3600 seconds	3,652	1.2%	Legacy infrastructure, some government sites

Table S4.2 — DNS TTL distribution analysis (312,847 responses, 72-hour test)

The 15.1% of records with TTLs below 60 seconds are the primary source of the 2.2% retroactively enriched connections (where the connection arrives after the dns_map entry has expired). At a 300-second TTL (the most common value, at 39.9%), a new TCP connection must be initiated within 5 minutes of the DNS response for the domain name to be available in the dns_map. For web browsing (where connections typically follow DNS responses within milliseconds), this is not a concern. The edge case is a long-running application that resolved a domain at startup and then makes new connections hours later after the TTL has expired — these connections will appear with no domain in KTA unless the application makes another DNS query.

Analysis of the geographic distribution of destination IPs across the 72-hour test provides insight into the typical traffic patterns of a software developer workstation in India. This data is derived from the COUNTRY and CC fields in /proc/traffic_analyzer_routes.

Country	Connection Count	Percentage	Primary Services
United States	51,247	60.8%	Google, AWS, Cloudflare, GitHub, npm, Slack
India	9,842	11.7%	BSNL DNS, Indian CDN nodes, local services
Netherlands	6,231	7.4%	Cloudflare EU, various CDN PoPs
Germany	4,817	5.7%	Hetzner cloud, EU-based CDNs
Singapore	4,201	5.0%	AWS ap-southeast-1, Cloudflare APAC
Japan	2,847	3.4%	Cloudflare APAC, various CDN PoPs
United Kingdom	1,923	2.3%	Various CDN PoPs, PyPI mirror
Other	2,204	2.6%	Various CDNs and content providers
Private / Unknown	1,000	1.2%	Local network, private IPs

Table S4.3 — Geographic distribution of network traffic destinations (72-hour test)

The dominance of United States destinations (60.8%) reflects the centralised hosting of major internet services (Google, AWS, GitHub, npm, Cloudflare) in the US, even for users in India. This has implications for data sovereignty: a significant fraction of developer traffic transits to US-based infrastructure regardless of the developer's intent. The 5.0% Singapore presence represents Cloudflare's APAC PoPs and AWS ap-southeast-1, the nearest major cloud region to India. The BGP Monitor would alert if any of these well-known destinations suddenly began routing through unexpected ASNs.

APPENDIX E Extended Glossary of Network and Kernel Terms

This appendix provides extended definitions for terms used throughout this report that may not be familiar to readers without a background in Linux kernel programming or advanced networking.

Term	Extended Definition
AF_NETLINK	Linux socket address family for kernel-userspace communication via netlink protocol. Used by iproute2, udev, a
ARP	Address Resolution Protocol — maps Layer-3 IP addresses to Layer-2 MAC addresses on local networks. Ope
CGNAT	Carrier-Grade NAT — NAT performed by ISPs using RFC 6598 (100.64.0.0/10) shared address space. Blocks
conntrack	Linux connection tracking subsystem (nf_conntrack). Maintains state for NAT and stateful firewall rules. Runs a
DKMS	Dynamic Kernel Module Support — framework for automatically recompiling kernel modules after kernel update
EDNS0	Extension Mechanisms for DNS (RFC 2671) — allows DNS messages larger than 512 bytes, enabling DNSSE
GFP_ATOMIC	Get Free Pages, Atomic — Linux memory allocation flag for interrupt/softirq context. Cannot sleep; returns NU
GRO	Generic Receive Offload — Linux kernel feature that merges multiple received packets into larger segments be
HWE	Hardware Enablement Stack — Ubuntu's mechanism for providing newer kernel versions on LTS releases. KT
jhash	Jenkins hash — non-cryptographic hash function used in the Linux kernel for hash table key distribution. Used
ktime_t	Kernel time type (64-bit nanosecond timestamp). Used throughout KTA for precise packet timing. ktime_get_ns
LSM	Linux Security Module — framework for mandatory access control policies. Modules include SELinux, AppArm
MMDB	MaxMind DB binary format — custom binary format for fast IP-to-record geolocation lookup using a binary tree
NAPI	New API — Linux network driver polling interface that batches multiple packets per interrupt to reduce overhea
netns	Network namespace — Linux namespace providing isolated network stacks. Docker uses one netns per contai
NIC	Network Interface Card — hardware component responsible for transmitting and receiving network frames.
nlmsg_multicast	Kernel function for broadcasting a netlink message to all subscribers on a multicast group. Returns -ESRCH (n
OOM	Out of Memory — kernel condition when physical and virtual memory are exhausted. KTA's GFP_ATOMIC allo
PoP	Point of Presence — a CDN's physical data centre location where cached content and network infrastructure is
RDATA	Resource Data — the data portion of a DNS resource record. For A records, RDATA is a 4-byte IPv4 address.
RSS	Receive Side Scaling — NIC feature that distributes incoming packets across multiple CPU cores based on pa
seq_file	Linux kernel virtual file framework for implementing /proc files that return large amounts of data via sequential r
sk_buff	Socket buffer (struct sk_buff) — primary kernel data structure representing a network packet including its head
skb_header_pointer	Kernel function that safely returns a pointer to a specific offset in an skb, handling non-linear (fragmented) skbs
softirq	Software interrupt — a deferred work mechanism in the Linux kernel for processing network packets, timers, a
spin_lock_bh	Acquire a spinlock while disabling bottom-half (softirq) processing on the current CPU. Required for locks shar

Term	Extended Definition
task_struct	Kernel data structure representing a process or thread. Contains PID, UID, comm (name), mm (memory map),
veth	Virtual Ethernet pair — a pair of connected virtual network interfaces used to connect Docker containers to the
WQ_UNBOUND	Workqueue flag allowing worker threads to run on any CPU. KTA's ta_resolver uses WQ_UNBOUND to avoid

Table F.1 — Extended glossary of terms

APPENDIX G Known Issues, Workarounds, and FAQ

Issue ID	Description	Workaround	Status
KTA-001	Module version string shows 7.0.0 while the rest of the traffic analyzer is 6.0	Cosmetic only; fix in next README update	Documentation only, fix in next README update
KTA-002	RouteHistory.cpp and RouteHistoryWidget.h/.cpp are 0-byte stub files	Route history is not implemented; use Heatmap for bandwidth history instead	Planned for v8.0
KTA-003	Empty stub files at repo root (arp, dns, ebpf, etc.)	These are placeholders from development; safe to ignore	Cosmetic, safe to ignore
KTA-004	SparklineDelegate cannot use Q_OBJECT, sparklines work without signals/slots	None required	Intentional, documented limitation
KTA-005	CONN_BURST false positives for browser connections	Add browser process name to CONN_BURST_WHITELIST in stats.c	Tuning ongoing
KTA-006	DNS-over-HTTPS blindspot for Firefox/Chrome	Disable DoH in browser settings, monitor system DNS	Architectural limitation
KTA-007	Module requires recompile after kernel update	Use DKMS (future work) or recompile manually: make -C /lib/modules/$(uname -r)/build M=$(pwd) modules	DKMS planned for v8.0
KTA-008	GUI must run as root (same privilege level as the kernel module)	By design; no privilege separation implemented yet	Privilege separation planned

Table G.1 — Known issues and workarounds

Q: Can KTA monitor traffic from inside Docker containers?

A: KTA monitors traffic on the host network namespace. Traffic between the host and containers via port-forwarded connections (-p flag in docker run) is visible. Traffic between containers on the same Docker bridge network is NOT visible, as it stays within the container network namespace. Traffic from a container to the internet (via the docker0 bridge and NAT) IS visible at the NAT boundary but is attributed to the docker-proxy process rather than the container process.

Q: Does KTA work on ARM (Raspberry Pi, Apple Silicon)?

A: The kernel module is architecture-agnostic in principle (uses only portable kernel APIs), and the Qt6 GUI is cross-platform. The route daemon requires the traceroute binary, which is available on ARM Linux. However, the module has only been compiled and tested on x86_64 (kernel 6.8.0). ARM cross-compilation using the target's kernel headers should work but has not been validated.

Q: Can KTA run on distributions other than Ubuntu 22.04?

A: Yes, in principle. The kernel module requires kernel 6.7+ for the rcu_dereference(mm->exe_file) pattern (kernel < 6.7 can use get_mm_exe_file()). The GUI requires Qt 6.2+ and CMake 3.22+. The route daemon requires Python 3.8+ and the geoip2 package. Fedora 39 and Arch Linux users have reported successful compilation with minor adjustments to include paths in the Makefile.

Q: Why does the Route Map show Bhopal as the source of all arcs?

A: The Bhopal coordinates (23.25°N, 77.41°E) are hardcoded as the origin of route arcs in RouteMapWidget.cpp, reflecting the deployment location during development. Future versions will determine the origin automatically from the system's external IP address via MaxMind lookup. Until then, users outside Bhopal can edit the ORIGIN_LAT and ORIGIN_LON

compile-time constants in RouteMapWidget.h to match their location.

Q: How is the trust score on the Trust tab calculated?

A: The trust score (0–100) is a weighted combination of: anomaly count (each active anomaly reduces score by 20); unresolved connection ratio (high ratio of PID=0 connections reduces score by up to 15); presence of foreign-country destinations in high-risk country list (reduces score by up to 20); and DNS enrichment ratio (processes with many un-enriched connections get a slight score reduction). Processes with no anomalies, fully resolved PIDs, and exclusively domestic destinations start at 100 and are reduced by each risk factor observed. The scoring algorithm is heuristic and intentionally simple; sophisticated reputation scoring is a future work item.

SUPPLEMENTARY CHAPTER 5 Ethical Considerations and Responsible Disclosure

KTA is a powerful tool that, by design, records every network connection made by every process on the monitored machine. This capability raises important privacy considerations that must be addressed before deploying the tool in any context involving other users, shared systems, or sensitive data.

On a single-user personal workstation (the primary intended deployment scenario), privacy concerns are minimal: the user is monitoring their own machine and has full knowledge and consent regarding the monitoring. The situation changes in multi-user environments (SSH servers, shared development machines) or corporate environments where employees use company-provided hardware.

In multi-user environments, KTA records connection data for all users' processes simultaneously, including the TCP/UDP ports they connect to (which can reveal which applications and services they are using), the domain names of their destinations (which can reveal browsing behaviour), and the volume of data transferred (which can reveal work patterns). In most jurisdictions, monitoring employees' network activity without their knowledge and consent is illegal or at minimum ethically problematic. Deployment of KTA on shared systems must comply with applicable data protection laws and organisational policies.

The following mitigations are recommended for responsible KTA deployment: (1) KTA should only be deployed on systems where the deployer has the legal right to monitor all users' network activity; (2) users of monitored systems should be informed that network monitoring is active; (3) the /proc files should be restricted to root-only access (chmod 0400) in multi-user environments to prevent one user from observing another's connections; (4) KTA's SQLite history database should be encrypted or access-controlled to prevent unauthorised retrospective analysis of network activity.

The fuzz testing of dns_parser.c (Section 7.E2) discovered three vulnerability classes. All three were internal to KTA and were fixed before public release. No vulnerabilities were found in the Linux kernel itself or in any third-party libraries used by KTA during the course of development.

The three DNS parser issues were classified as low-severity based on their exploitability analysis: to trigger any of the three bugs, an attacker would need to be able to send malformed DNS responses to the monitored machine. This requires either control of the DNS server being queried (a significant precondition) or a man-in-the-middle position on the network path between the monitored machine and its DNS resolver. In either case, the attacker already has a high level of network access and the KTA vulnerability adds minimal additional risk. Nonetheless, all three issues were fixed to maintain defensive code quality.

The GitHub repository's SECURITY.md file provides a responsible disclosure policy for KTA: security issues should be reported privately via GitHub's private vulnerability reporting feature before public disclosure, with a 90-day disclosure timeline consistent with Google Project Zero's policy. The author commits to acknowledging reports within 48 hours and providing a fix

or workaround within 30 days for critical vulnerabilities.

KTA is released under the GNU General Public License version 2 (GPLv2), the same licence used by the Linux kernel. This choice is motivated by two factors: (1) GPLv2 compatibility with the kernel's EXPORT_SYMBOL and EXPORT_SYMBOL_GPL API — kernel modules that use GPL-only symbols (marked EXPORT_SYMBOL_GPL) must themselves be GPLv2 licensed; (2) the copyleft nature of GPLv2 ensures that any modifications or improvements made by third parties must be shared under the same terms, benefiting the community.

The Qt6 GUI (Layer 3) is linked against Qt6 under the LGPL version 3, which allows the GUI to be distributed without being subject to GPL requirements, as long as the user can relink against a modified version of Qt. Since the GUI is a separate executable from the kernel module, the GPL of the kernel module does not propagate to the GUI codebase. The route daemon (Layer 2) is released under the MIT licence for maximum flexibility, as it contains no kernel-linked code and may be adapted for use with other monitoring backends.

SUPPLEMENTARY CHAPTER 6 Future Architecture: KTA v8.0 Design Vision

The most requested enhancement from early testers of KTA is automatic recompilation when the kernel is updated. Dynamic Kernel Module Support (DKMS) provides exactly this capability: a DKMS-registered module is automatically recompiled and installed when a new kernel is installed via the package manager. Adding DKMS support requires creating a dkms.conf file specifying the module name, version, and build instructions, and registering the module with dkms add. The estimated effort is 2–3 hours of additional packaging work.

```
# dkms.conf for KTA v8.0 (planned) PACKAGE_NAME="traffic-analyzer"
PACKAGE_VERSION="8.0" BUILT_MODULE_NAME[0]="traffic_analyzer"
BUILT_MODULE_LOCATION[0]="kernel_module/src"
DEST_MODULE_LOCATION[0]="/updates/dkms" MAKE[0]="make -C ${kernel_source_dir}
M=${dkms_tree}/${PACKAGE_NAME}-${PACKAGE_VERSION}/kernel_module/src modules"
CLEAN="make -C ${kernel_source_dir}
M=${dkms_tree}/${PACKAGE_NAME}-${PACKAGE_VERSION}/kernel_module/src clean"
AUTOINSTALL="yes"
```

KTA v8.0 will include systemd unit files for both the kernel module (via a oneshot service that runs insmod at boot and rmmod at shutdown) and the route daemon (a standard daemon service with restart-on-failure).

```
[Unit] Description=Kernel Traffic Analyzer Route Daemon
After=network-online.target Wants=network-online.target [Service] Type=simple
ExecStart=/usr/bin/python3 /usr/lib/kta/ta_route_daemon.py Restart=on-failure
RestartSec=5 User=root StandardOutput=journal StandardError=journal [Install]
WantedBy=multi-user.target
```

Full IPv6 support in v8.0 requires extending four key data structures: flow_key (replace __be32 src_ip/dst_ip with __be32[4] src_ip6/dst_ip6), traffic_entry (corresponding address field update), dns_map (store AAAA records in addition to A records), and all /proc format strings (display IPv6 addresses in standard colon-separated notation). The make_canonical() function requires updating to compare 128-bit addresses correctly (compare as unsigned 128-bit integer or as two sequential 64-bit comparisons).

The netfilter hook registration requires adding NFPROTO_IPV6 hooks alongside the existing NFPROTO_IPV4 hooks. The dns_parser.c requires extending to handle AAAA records (type 0x001C, RDLENGTH=16, 16-byte IPv6 RDATA). The route daemon requires extending to handle IPv6 destinations in traceroute (traceroute6 -T). The RouteMapWidget requires updating to handle IPv6 geolocation (MaxMind's GeoLite2-City supports IPv6 natively). The estimated total effort for full IPv6 support is 5–8 developer days.

The web dashboard future work item (Section 5.2) envisions a lightweight embedded HTTP server in the route daemon (using Python's built-in http.server or the aiohttp framework) that serves a single-page web application. The SPA (Single Page Application) would connect to a

WebSocket endpoint that streams real-time netlink events from the kernel module. This would allow monitoring from any device on the local network without installing the Qt6 GUI.

The data pipeline for the web dashboard would be: kernel module netlink multicast → Python netlink subscriber in route daemon → JSON serialisation → WebSocket broadcast → browser-side JavaScript → D3.js or Chart.js visualisations. The web dashboard would initially provide a subset of KTA's functionality (connections table, process summary, anomaly alerts) with the full GUI retained for advanced features (route map, BGP monitor, firewall management). Security note: the WebSocket server must bind only to localhost by default to prevent exposure to the local network.

The ML-based anomaly detection future work item (Section 5.2) envisions replacing the five threshold-based detectors with an online Isolation Forest model trained on per-process feature vectors. The feature vector for each process would include: (rate_out_bps, rate_in_bps, new_conns/sec, unique_dst_ports/sec, syn_ratio, total_conns, unique_countries/hour, dns_resolution_rate). The Isolation Forest would learn the normal range of each feature from the first 24 hours of monitoring, then flag deviations as anomalies with a continuous anomaly score rather than a binary flag.

Implementation would use scikit-learn's IsolationForest in the Python route daemon (which already runs as a Python process), with the model receiving feature vectors from a new /proc/traffic_analyzer_features file updated every 5 seconds. The model would be persisted to disk using joblib and retrained weekly to adapt to changing normal behaviour. The binary threshold-based detectors would be retained as a fallback for the training period (first 24 hours) and for extreme-value anomalies that the ML model may not catch (e.g., a SYN rate of 10,000/sec is unambiguously anomalous regardless of learned baseline).

SUPPLEMENTARY CHAPTER 7 Project Management and Academic Context

KTA was developed using a mix of open-source tools freely available on Ubuntu 22.04. The primary code editor was Visual Studio Code with the C/C++ extension for syntax highlighting and IntelliSense (though kernel module code cannot use standard LSP completion due to the absence of a compile_commands.json compatible with the Kbuild system). The kernel module was compiled and loaded on the same machine as the development environment, with dmesg -w running in a dedicated terminal to monitor kernel log output during testing.

Git version control was used throughout the project with a conventional commit message format (feat:, fix:, docs:, refactor:, test: prefixes). The GitHub repository was maintained publicly from version 5.0 onwards. GitHub Actions CI was configured to run the userspace shim tests (Section 7.1) on every push, providing early warning of regressions in the dns_parser, make_canonical(), and anomaly threshold logic. The Qt6 GUI build was not included in CI due to the build time overhead of downloading and compiling Qt6 in the CI environment.

Tool	Version	Purpose
Visual Studio Code	1.87	Primary code editor
GCC	11.4.0	Kernel module and GUI compilation
Clang/LLVM	14.0	Static analysis (clang-tidy) and fuzz testing corpus generation
GDB + kgdb	12.1	Kernel module debugging (via kgdb on second machine)
Valgrind	3.19.0	Userspace shim memory error detection
AFL++	4.09	DNS parser fuzz testing
checkpatch.pl	Kernel 6.8	Kernel coding style compliance
sparse	0.6.4	Kernel static analysis (make C=2)
Git	2.34.1	Version control
GitHub Actions	N/A	CI for userspace unit tests
Qt Creator	11.0	Qt6 GUI layout design and QML prototyping
SQLite Browser	3.12	Inspecting history.db during development
Wireshark	4.2.3	DNS response capture for fuzz test corpus

Table S7.1 — Development tools and versions

The KTA codebase was analysed using cloc (Count Lines of Code) to provide a breakdown of code, comment, and blank line distribution across the three layers.

Layer / File	Language	Code Lines	Comment Lines	Blank Lines	Total
Kernel Module (all .c/.h)	C	3,124	312	287	3,723

Layer / File	Language	Code Lines	Comment Lines	Blank Lines	Total
module_main.c	C	98	24	18	140
netfilter_hook.c	C	157	31	22	210
packet_parser.c	C	389	47	38	474
stats.c	C	447	52	44	543
proc_interface.c	C	331	38	31	400
dns_parser.c	C	173	24	19	216
Other .c files	C	1,529	96	115	1,740
Route Daemon	Python	287	31	24	342
Qt6 GUI (all .cpp/.h)	C++	7,847	612	524	8,983
CMakeLists.txt	CMake	124	8	12	144
Shell test scripts	Bash	312	28	35	375
Python test shims	Python	487	42	38	567
TOTAL	—	12,181	1,033	920	14,134

Table S7.2 — Lines of code analysis (cloc output)

The comment-to-code ratio of approximately 8.5% is slightly below the Linux kernel's typical 12–15% but above the level observed in most student projects. The kernel module has the highest comment density (10%) reflecting the importance of documenting subtle synchronisation decisions. The GUI has a lower comment density (7.8%) because Qt's model-view pattern and signal-slot mechanism are largely self-documenting through the framework's naming conventions.

This project makes the following original contributions to the field of Linux network security and observability:

- **Unified kernel observability architecture:** The three-layer architecture (kernel module + Python daemon + Qt6 GUI) provides a reference design for comprehensive Linux network monitoring that integrates capabilities previously requiring separate tools.
- **In-kernel DNS pipeline:** The technique of parsing DNS responses in the NF_INET_LOCAL_IN netfilter hook before connection tracking, enabling immediate domain enrichment at connection creation time, is to the author's knowledge not documented in prior open-source implementations.
- **4G-optimised route tracing:** The integration of TCP-mode traceroute (port 443) with MaxMind GeoLite2 enrichment into a kernel-aware route daemon, specifically validated for carrier-grade NAT environments common in Indian 4G deployments, addresses a practical gap in existing tools.
- **Four-level PID attribution waterfall:** The hierarchical sock_cache → inode_cache → flow_cache → full resolver design achieves 96.8% attribution accuracy with < 0.05% CPU

overhead, providing a practical reference implementation for per-process kernel monitoring.

- **Open-source reference implementation:** The complete, production-tested codebase is publicly available on GitHub, providing an educational resource for advanced Linux kernel programming topics not commonly demonstrated in combined academic-practical projects.

The author gratefully acknowledges the following resources and communities that contributed to the successful completion of this project:

The Linux kernel developer community, whose extensive documentation, publicly available source code, and responsive mailing lists (particularly netdev@ and netfilter-devel@) provided authoritative answers to implementation questions. The kernel.org documentation at https://www.kernel.org/doc/html/latest/ was referenced extensively, particularly the Netfilter, workqueue, and RCU sections.

The MaxMind team for providing the GeoLite2 databases under a Creative Commons licence, enabling geographic enrichment without commercial licensing costs. The Qt community and The Qt Company for Qt6's comprehensive documentation and the Qt Creator IDE, which significantly accelerated GUI development. The AFL++ team for developing and maintaining the world-class fuzzer that identified the DNS parser vulnerabilities.

Finally, the author acknowledges the formative experience of working through a limited 4G data connection in Bhopal, which provided both the motivation and the real-world testing environment for KTA. The constraints of limited bandwidth, carrier-grade NAT, and the need to understand exactly which application was consuming the data allocation drove every major design decision in the project.
